Abstract: We report the superconducting properties between a conventional strong-coupled Pb and weak-coupled Sn superconductor. A series of Sn_rPb_{1-r} nanoalloys with various compositions r were synthesized, and their superconducting properties were measured using superconducting quantum interference devices (SQUIDs) magnetometer. Our results reveal a superconducting proximity effect (SPE) between immiscible Sn and Pb granules in the range of r = 0.2~0.9, as a weak superconducting coupling can be established with the coexistence of phonon hardening and increased Ginzburg–Landau coherence length. Furthermore, our results provide new insights into improving the study of the superconducting proximity effect introduced by Sn doping.

Keywords: superconducting proximity effect; electron–phonon coupling; superconductor; SnPb bimetallic system

1. Introduction

The concept of the proximity effect between a superconductor (SC) and a standard metal (NM) induced superconductivity was developed in 1960 [1] At the interface of SC/NM, one can observe the breaking of the Cooper pair in the SC at the length scale of the coherence length (ξ) across the interface. The applying boundary condition at the interface, the pairing amplitude $F = \langle \Psi_\uparrow \Psi_\downarrow \rangle$, is suppressed at the surface of the SC and enhanced in NM. Recently, much attention has been paid to search for Majorana fermions (MFs) in condensed matter systems using a conventional *s*-wave SC-3D topological insulator (TI), where a proximity-induced state resembling a spinless superconductor is expected to occur [2]. Lu et al. investigated the conductance spectra of Sn-Bi_2Se_3 interface junctions down to 250 mK and in different magnetic fields [3]. As a result, a proximity-effect-induced chiral superconducting phase is found and formed at the interface between the superconducting Sn and the strong spin-orbit coupling material Bi_2Se_3.

Moreover, a Josephson current can be established over several microns in the lateral direction between two Pb- or Sn-electrodes on the Bi_2Te_3 surface, demonstrating that superconducting quantum interference devices can be constructed based on proximity-effect-induced superconductivity [4,5]. *The interplay of* BCS superconductivity and nontrivial band topology is expected to give rise to the search for *Majorana fermion* quasiparticles in condensed matter systems. Therefore, knowledge of the precise electron–phonon and superconducting coupling strength of Pb/Sn is essential in explaining the proximity effect.

In the last two decades, researchers have shown interest in the Pb/Sn system to study the superconducting proximity effect (SPE) [6–8]. The nanoscale system has attracted further interest to study the size effects on the superconducting to normal state transition, on the flux-line penetration in a spatially confined region, or on the phase-slip mechanism [6]. In bimetallic superconducting nanoalloys with a heterogeneous distribution of grains more minor than the ξ of the constituent elements, the superconducting proximity effect (SPE) can alter the superconducting properties. In this work, we report the observation of the

SPE on the superconducting properties of Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) bimetallic nanoalloys. Granular Sn can be randomly distributed within the Pb matrix during the alloying process. In this scenario, if the grain size is smaller than the superconducting characteristic length scales, then studying SPE can give more insight into the superconducting properties of immiscible bimetallic nanoalloys.

2. Methods

Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) superconductors were prepared using a physical solid-state reaction. This Sn/Pb concentration tuning alters the crystal structure, thereby changing the superconducting properties. Surface morphological analysis and atomic percentage calculation of all the samples were performed by field-emission scanning electron microscopy (FE-SEM) using a JEOL JSM-6500F microscope (JEOL Ltd., Tokyo, Japan). Energy dispersive spectroscopy (EDS; Inca x-sight model 7557, Oxford Instruments, Abingdon, Oxfordshire, UK) was utilized to estimate the atomic percentages of the constituent elements. Energy-dispersive spectroscopy (EDS) is a valuable technique for estimating the samples' atomic rates of constituent elements. To study the alloying effect of Sn and Pb on structural properties, synchrotron radiation X-ray diffraction (SR-XRD) of the nanoalloys was carried out using synchrotron radiation beamline BL-01C2 at the National Synchrotron Radiation Research Center (NSRRC) in Taiwan with an incident wavelength $\lambda = 0.7749$ Å.

3. Results

3.1. Elemental Analysis and EDS Mapping of SnPb

Figure 1a shows the typical EDS spectra of a series of Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) bimetallic nanoalloys, which are shifted vertically for clarity. The series of Sn and Pb constituent elements observed in EDS spectra are assigned to Pb-$M\alpha_1$, Sn-$L\alpha$, Sn-$L\beta_1$, and Sn-$L\beta_2$. The weak peak of C-$K\alpha1$ and O-$K\alpha1$ in the low energy regions originated from the carbon tape used for mounting the sample and surface oxygen, respectively. Figure S1a–k (Supporting Information) presents the EDS mapping with SEM images of Sn_rPb_{1-r} bimetallic nanoalloys, where red and green represent the atomic percent of Pb and Sn, respectively. Figure 1b shows the plot of atomic % of Sn concerning composition r, which increases linearly with a slope of 89 (10) atomic percentage with Sn composition (at. %/r). The observed slight discrepancy of at. % with initial composition r could be due to the inhomogeneous distribution of constituent elements. The phase diagram is very sensitive to preparation conditions, so slight changes in the temperature, pressure, or initial composition can change the weight percent of the constituent phases for each nanoalloy. The EDS mapping images of Sn_rPb_{1-r} nanoalloys show the distribution of segregated Sn (bright green color) and Pb (red color) elements with grain size varying from $<d>$ = 121 (10)~46 (3) nm. The observed discrepancy of atomic % with initial composition is due to three-dimensional inhomogeneous distributions of segregated grains of Sn and Pb. In such a scenario magnetization, M(T) can be fitted with the London equation of granular sized $<d>$, which will be discussed in the magnetization section.

**Figure 1.** (**a**) Typical EDS elemental spectra reveal a series of peaks associated with Sn and Pb elements, verifying that the Sn_rPb_{1-r} bimetallic nanoalloys contain only Sn and Pb elements; (**b**) atomic % of Sn with respect to the initial composition of Sn_rPb_{1-r} bimetallic nanoalloys.

3.2. Crystal Structural and X-ray Refinement Analysis of SnPb

A 2D plot of the X-ray diffraction pattern of Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) nanoalloys over a narrow scattering range of 2θ is shown in Figure 2a, where the vertical axis represents the composition r. The "contour color fill" function provided in the Origin software was utilized to draw a 2D plot in which different colors were used to differentiate the peak intensities of the diffraction pattern. From the above 2D plot, for r = 0.01~0.1, nuclear peaks (111) and (200) indexed based on *Fm-3m* (No. 225) become visible, indicating the formation of a Pb-Sn solid solution having the same structure as that of virgin Pb, as shown in Figure 2b. Since the atomic radii of Sn (140 pm) are smaller than Pb (175 pm), Sn can occupy interstitial sites in the Pb lattices resulting in the formation of the interstitial solid solution, as shown in Figure 2c [9–14]. Sn_rPb_{1-r} nanoalloys that contain 0~2 at. % Sn behave like the copper-nickel alloys; a single solid solution α-Pb phase forms during solidification [12,13]. These nanoalloys are strengthened by solid-solution strengthening, strain hardening, and controlling the solidification process to refine the grain structure. A previous comprehensive study[11] reported that the growth mechanism of SnPb solid solution is due to the grain boundary migration and sliding occurring systematically, giving rise to a series of migration markings on the surface of deformed specimens. However, for $r \geq 0.2$, the Pb phase becomes unstable and shows additional diffraction picks (101) and (200) indexed based on *I4₁/amd* (No. 141) of the Sn phase, as shown in Figure 2d. For further detailed structural analysis, Rietveld refinement of the XRD pattern of Sn_rPb_{1-r} bimetallic nanoalloys was carried out using the GSAS software package [15,16]. All the fitting parameters, including the lattice constant and the weight percent of constitute phases, are tabulated in Table 1. The refined patterns of the nanoalloys are shown in Figure 3a (spectra are shifted vertically for clarity). From refined XRD spectra of Sn_rPb_{1-r} nanoalloys, immiscible phases of Sn and Pb were observed for all compositions except the region of r = 0.01~0.1, which is in good agreement with the reported phase diagram of the Sn-Pb system [17]. From the fitted values of the lattice constant of the Pb-phase and the Sn Phase vs. r value shown in Figure 3b,c respectively, it can be observed that the Sn doped Pb (r = 0.01) results in a lattice expansion of 0.19% (Figure 3b). For the highest Sn concentration (r = 0.99), both Sn (0.19% along basal plane and *c*-axis) and Pb (0.06%) show lattice expansion (Figure 3c). The observed expansions from both Sn and Pb phases in nanoalloys could be because of the strain effect, as the thermal expansion coefficient for Sn (22×10^{-6} m/mK) is lower than Pb (28.9×10^{-6} m/mK). The crystallite size of both Sn and Pb phases were calculated using the Scherrer method: $D = \frac{k\lambda}{\beta \cos \theta}$ nm, where k is constant, θ is the angle of diffraction, λ is the incident wavelength ($\lambda = 0.7749$ Å), and β is

the full width at half maximum. The obtained crystallite sizes are in nanometers as shown in Table 1, and it can be observed that the Sn-doped Pb (r = 0.01 to 0.99) results in a change in crystallite size (Figure 3b).

3.3. Temperature Dependence of Magnetization

Sn and Pb are weak- and strong-coupled type-I superconductors, respectively. Therefore, studying the low-temperature properties of Sn-Pb bimetallic nanoalloys will give further insight into the effect of alloying on the SC properties [17]. Furthermore, if the grain size of randomly distributed Sn and Pb in the immiscible bimetallic nanoalloys is smaller than their respective coherence length, it can further alter the SC properties due to SPE. Therefore, we have applied magnetic field and temperature-dependent magnetization measurements to study the SC properties using a magnetometer (Quantum Design MPMS VSM SQUID). A temperature dependence series of magnetization measurements between T = 2 to 8 K using an applied magnetic field of H_a = 100 Oe in the ZFC and FC modes for r = 0.01, 0.7, 0.8, 0.9, and 0.99 SnPb nanoalloys are shown in Figure 4a–e, where r = 0.1~0.6 are shown in Figure S2 (Supporting Information). The observed step-like behavior of M(T) curves for r = 0.01 indicates that magnetic flux cannot penetrate the materials in a small external field of 100 Oe. However, with an increased Sn concentration, the broadening of M(T) was observed, which could be because of the inhomogeneous distribution of Pb in the Sn matrix. Interestingly, a one-step-like transition was observed from nanoalloys with initial composition r = 0.01–0.7. However, nanoalloys with r ≥ 0.8 show two-step-like transitions. The M(T) curves can be described effectively using a modified London equation with free fitting parameter p, assuming that alloying of Sn and Pb resulted in the formation of SC grains of size <*d*> obtained from the EDS mapped image of Sn_rPb_{1-r} nanoalloys [18,19]. The analysis of mean granular size <*d*> of segregated Sn (bright green color) and Pb (red color) elements obtained from the EDS mapping results are tabulated in Table 2. From the modified London equation, the DC magnetization can be written as:

$$M(T) = a + H_a \times \frac{-1}{4\pi} \left\{ \frac{-3}{2\rho} \left[1 - 6\left(\frac{\lambda_L}{<d>}\right) coth\left(\frac{<d>}{2\lambda_L}\right) + 12\left(\frac{\lambda_L}{<d>}\right)^2 \right] \right\} \quad (1)$$

where ρ is mass density which lies between the density of bulk Pb (11.35 g/cm^3) and Sn (7.3 g/cm^3) concerning initial composition, and λ_L is the London penetration depth defined as

$$\lambda_L(T) = \lambda_L(0)[1 - (T/T_C(0))^p]^{-1/2} \quad (2)$$

where $\lambda_L(0)$ is a penetration depth measured at zero temperature. A good fit for the BCS predictions can be obtained using $p = 2$ for s-wave type superconductors and $p = 3/4$ for d-wave type superconductors. The power factor p defines the distribution of the transition temperature, i.e., the higher the value of p (≥ 1), the steeper the distribution of transition temperature will be. In such a scenario, the bulk-like magnetization M(T) (i.e., steep transition), can be well-fitted using $p > 4$. In these composite granular nanoalloys, the best fitting is obtained using p as a free-fitting parameter. The fitted value of p lies between 10 to 2 concerning the applied magnetic field. The obtained high value of p in a low external magnetic field is due to the flow of the shielding current around the surface of the alloy excluding the applied field detail which has been discussed in our previous work [20–22].

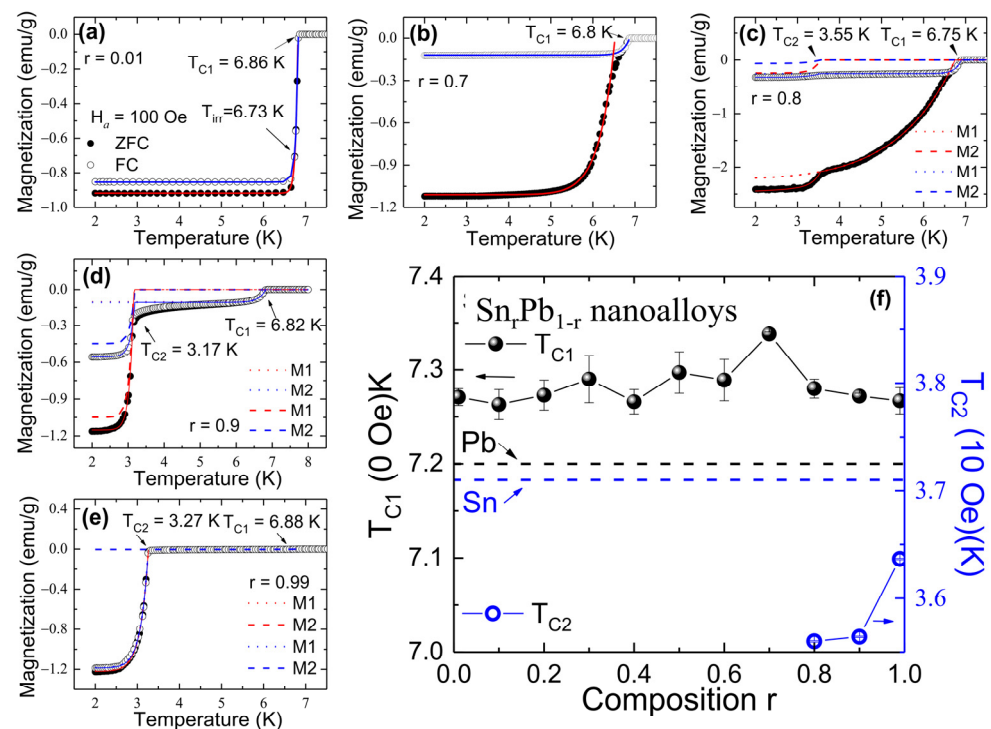

Figure 4. (**a**–**e**) temperature dependence of magnetization measured between 2 to 8 K in an external magnetic field of H_a = 100 Oe in the ZFC and FC modes for r = 0.01, 0.7, 0.8, 0.9, and 0.99 nanoalloys. The red and blue solid curve presents the fitted curve of the modified London expression to the data; (**f**) fitted value of transition temperature T_{C1} (black sphere, see Section 3.5) and T_{C2} (blue circle, measured at 10 Oe) as a function of the initial composition. The horizontal dashed lines represent the reported values of T_C from bulk Pb and Sn.

The solid line shown in Figure 4a–e is the fitted curve obtained from the modified London equation, revealing a diamagnetic Meissner state below T_{C1}(100 Oe) = 6.8 (2) K (maximum, r = 0.7). At higher Sn concentration (r $\geq$ 0.8), a slight kink occurs in the low-temperature region at T_{C2}, signaling the onset of a small superconductivity gap contributed from the Sn phase. The observed two-step behavior in r $\geq$ 0.8 nanoalloys can be described using a superposition of the London equation for Pb(M1) and Sn(M2), showing two transitions, T_{C1} and T_{C2}. The fitted value of T_{C1}(0 Oe) (for further details see Section 3.5) and T_{C2} (10 Oe) concerning initial composition r is plotted in Figure 4f. Detailed fitting parameters to M(T) curves are summarized in Table 2. The T_{C1} and T_{C2} values at 0 and 10 Oe magnetic fields are slightly higher than that of the of reported values from bulk Pb and Sn (7.2 K and 3.7 K, respectively), possibly because of the strain effect observed from the X-ray diffraction refinement [20,21].

Table 2. Summary of obtained physical parameters: mean granular size *<d>*, critical field $H_{C1}(0)$, upper critical field $H_{C2}(0)$, and thermodynamical critical field $H_C(0)$, Ginzburg–Landau coherence length $\xi_{GL}(0)$, Ginzburg–Landau parameter k, penetration depth $\lambda(0)$, and mean free path ℓ of Sn_rPb_{1-r} nanoalloys estimated within the superconducting state.

3.4. Critical Fields and Theoretical Analysis

To understand the applied magnetic effect on the superconducting properties of Sn_rPb_{1-r} bimetallic nanoalloys, the field dependence of magnetization $M(H_a)$ below T_C over ± 1200 Oe field was carried out. Figure 5a–d shows the four selected $M(H_a)$ loops measured at 2 K for r = 0.01, 0.7, 0.9, and 0.99 nanoalloys, respectively. Details of the $M(H_a)$ loops measured at 2 K for r = 0.1 to 0.6 nanoalloys are shown in Figure S3 (Supporting Information). Type-I-like $M(H_a)$ loops were observed for r = 0.01 and 0.99, whereas $M(H_a)$ loops of all remaining nanoalloys show type-II-like behavior reflecting the character of the magnetic flux penetration into the superconducting nanoalloys. The Meissner effect was observed in the low field region from $M(H_a)$. It deviated from linearity after reaching the lower critical field H_{C1}, as shown in Figure 5a–d, where solid lines represent the linear fit. Above the upper critical field H_{C2} (pointed by the arrow in Figure 5a–d), magnetization $M(H_a)$ eventually turns to M = 0 states. To estimate the temperature dependency of H_{C1} and H_{C2}, $M(H_a)$ loops were measured using a protocol of H_a= 0 Oe → +900 Oe → 0 Oe at various temperatures, as shown in Figure 5e–h for r = 0.01, 0.7, 0.9, and 0.99 nanoalloys, respectively. Details of the $M(H_a)$ loops measured at various temperatures for r = 0.1 to 0.6 nanoalloys are shown in Figure S4 (Supporting Information). Figure 5i,j shows the T/T_{C1} dependency of H_{C1} and H_{C2}, which can be described using

$$H_{C1}(T) = H_{C1}(0)\left(1 - \left(T/T_{C1}(0)\right)^2\right) \qquad (3)$$

and

$$H_{C2}(T) = H_{C2}(0)\left(1 - \left(T/T_{C1}(0)\right)^2\right) \qquad (4)$$

where $H_{C1}(0)$ and $H_{C2}(0)$ are the lower and upper critical fields at zero temperature, respectively. The fit by using the above former expression yields a maximum field of $H_{C1}(0) = 596(7)$ Oe from $Sn_{0.2}Pb_{0.8}$ nanoalloy and the minimum of $H_{C1}(0)$~240(5) Oe from $Sn_{0.99}Pb_{0.01}$ nanoalloy. The $H_{C1}(0)$ values for other nanoalloys lie between these two critical fields and are tabulated in the supporting information of Table 2. We also note that for r = 0.8, 0.9, and 0.99 nanoalloys, due to the appearance of the second superconducting gap of Sn, it is difficult to estimate $H_{C1}(0)$ values. Contrary to H_{C1}, H_{C2} for Sn_rPb_{1-r} nanoalloys shows typical type-II superconductor temperature dependency with linear variation near $T_C(0)$ and tends to saturate at low temperatures. The fit by using the above later expression yields a maximum field of $H_{C2}(0) = 886(16)$ Oe from $Sn_{0.2}Pb_{0.08}$ nanoalloy and a minimum value of $H_{C2}(0) = 824(8)$ Oe from $Sn_{0.01}Pb_{0.99}$ nanoalloy.
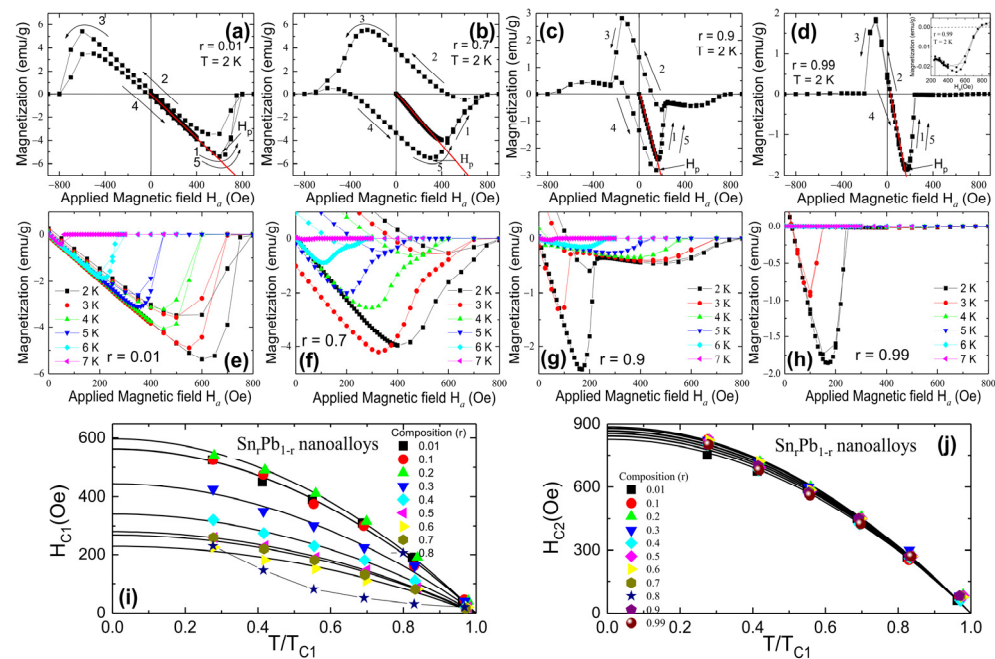

Figure 5. (**a**–**d**) isothermal magnetization M(H$_a$) loops measured at 2 K for r = 0.01, 0.7, 0.9 and 0.99 nanoalloys. The solid red line is the linear fit to the first magnetization curve. Arrows mark the observed irreversible field; (**e**–**h**) the M(H$_a$) loops measured using a protocol of H$_a$= 0 Oe $\rightarrow$ +900 Oe $\rightarrow$ 0 Oe at higher temperature up to 7 K for r = 0.01, 0.7, 0.9, and 0.99 nanoalloys; (**i**,**j**) lower and upper critical field as a function of temperature. Solid lines fit the power law mentioned in the text.

Using the fitted values of H$_{C1}$(0) and H$_{C2}$(0), in the extreme type-II limit, within the framework of Ginzburg–Landau (GL) theory [23], the GL superconducting coherence ξ_{GL} length and magnetic penetration depth $\lambda(0)$ can be estimated by using $\xi_{GL}(0) = \sqrt{\Phi_0/2\pi H_{C2}(0)}$ and $\lambda(0) = \kappa(0)\xi_{GL}(0)$, where $\Phi_o = \frac{h}{2e} = 2.0678 \times 10^9$ OeÅ^2 is the quantum flux and $\kappa(0) = \sqrt{H_{C2}(0)/2H_{C1}(0)}$. The small value of H$_{C2}$(0) implies a long superconducting GL coherence length $\xi_{GL}(0)$ = 632 Å, $\lambda(0)$ = 541 Å (r = 0.01), and the similarly large value of H$_{C2}$ implies a short $\xi_{GL}(0)$ = 609 Å, $\lambda(0)$ = 525 Å (r = 0.2). The estimated GL parameter $\kappa(0)$ for corresponding r = 0.01 and 0.2 nanoalloys are 0.856 and 0.862, indicating type-II superconductivity. In GL theory, a superconductor is called a type-I superconductor if $\kappa(0) < \frac{1}{\sqrt{2}}$ and type-II superconductor if $\kappa(0) > \frac{1}{\sqrt{2}}$. When the order parameter throughout the sample is constant, the GL model reduces to the London model. Furthermore, the value of $\lambda(0)$ shows increasing behavior with the increase of r, possibly due to an increase in disorder. The observed enhanced value of $\lambda(0)$ = 828 Å for r = 0.99 indicates the highest degree of disorders in this series of nanoalloys. Magnetic measurement is performed with an applied magnetic field H$_a$ lower than the value of H$_{C1}$(0), shielding current flows around the sample surface to exclude H$_a$. In this case, penetration depth λ is obtained as the penetrating length of H$_a$ at the sample edge. However, magnetic measurements were performed with H$_a$ larger than H$_{C1}$(0) (mixed state), and the field penetrated the sample as vortices. In this case, λ is given as a decay length of H$_a$ from the center of the vortex. In conjunction with increasing $\lambda(0)$ carrier mean free path, ℓ at low-temperature T = 2 K can be estimated from GL relation

$$\frac{1}{\ell} = \frac{\xi_o}{0.882}\left[\frac{0.546}{\xi_{GL}^2(0)\left(1 - \frac{T}{T_{C1}}\right)} - \frac{1}{\xi_o^2}\right] \tag{5}$$

where ξ_o is the BCS coherence length [20,24]. The lowest value of ℓ = 1260 Å was observed for r = 0.2 nanoalloy. In addition, the calculated values of the thermodynamic critical field, H$_{TC}$(0) $\approx \sqrt{H_{C1}(0)H_{C2}(0)}$, shows a maximum value of ~727 Oe for r = 0.2 nanoalloy.

The estimated superconducting parameters for all the SnPb nanoalloys are summarized in Table 2. The observed value of ℓ is higher than that of the atomic spacing of Pb and Sn, indicating that the observed slight enhancements in the values of T_C could be due to the strain effect [21,22,25–28]. Furthermore, note that estimated values of $\xi_{GL}(0)$ and ℓ for both high or lower (i.e., Sn concentration) are close to the superconductor parameter of pure Pb, which could either be due to segregating of a fraction of Pb within Sn matrix or superconducting the proximity effect. Therefore, with the increase of Sn concentration, coupling strength could show decreasing behavior [29].

3.5. Superconducting Coupling Strength

For further detailed analysis, field-dependent ZFC M(T) curves were measured with different external magnetic fields H_a varying from 10 to 700 Oe and fitted with the modified London equation as shown in Figure 6a–e. More details of the M(T) measured at various applied magnetic fields for r = 0.1 to 0.6 nanoalloys are shown in Figure S5 (Supporting Information). The H_a dependency of T_{C1} shown in Figure 6f can be fitted using $T_{C1}(H_a) = T_{C1}(0)[1 - H_a/H_C(0)]^{\gamma}$, where γ is a fitting parameter. The obtained highest critical field $H_C(0)$ at T = 0 K, zero-field critical temperature $T_{C1}(0)$, and the fitting parameter γ are tabulated in Table 3. The fitted value of $H_C(0)$ represents the upper critical field, and its value matches very well with the fitted value of $H_{C2}(0)$ (Equation (4); Table 2). The relative coupling strength of a superconducting system can be revealed in the deviation of $H_C(T)/H_C(0)$ from the parabolic dependence of $1 - (T/T_{C1})^2$ [30]. It is known that weakly coupled systems yield negative deviations, while strongly coupled systems yield positive deviations (marled as red color) [31]. A negative deviation (marked as blue color) was observed for all Sn_rPb_{1-r} nanoalloys, as shown in Figure 7, which can be described using the α-model defined as $\frac{H_C(T)}{H_C(0)} = \left[1 - \left(\frac{T}{T_{C1}}\right)^{\alpha}\right]$, where the fitting parameter $\alpha = \Delta_o/k_B T_{C1}$ represents the coupling strength (summarized in Table 3). From Figure 7, we note that coupling strength α subverts with an increase of Sn concentration and shows a minimum of $\alpha = 1.821(3)$, $T_{C1}(0) = 7.272(3)$ K for r = 0.9 nanoalloy, which is more vital than BCS coupling strength of 1.747 [32,33]. The observed subverted coupling strength as compared to strong-coupled Pb is possibly due to the propagation of SPE through the weak-coupled Sn matrix. The observed results suggest that the coupling strength of strong-coupled Pb can be tuned through SPE in Sn_rPb_{1-r} bimetallic nanoalloys. A slight enhancement of superconducting transition temperature (T_C) was observed from the magnetization, revealing a main diamagnetic Meissner state below $T_C = 7.338(2)$ K and a critical field of $H_C = 852(5)$ Oe from $Sn_{0.7}Pb_{0.3}$ mixed-phase nanoalloy associated with strain effect.

Table 3. Summary of obtained physical parameters, such as critical temperature $T_{C1}(0)$, critical field $H_C(0)$, fitting parameters γ, coupling strength α, phonon energy ω_{ln}, and electron–phonon coupling constant λ_{ep} of Sn_rPb_{1-r} nanoalloys, estimated within the superconducting state.

| Sample#	Sn_rPb_{1-r}	$T_{C1}(0)$ (K)	H_C (Oe)	γ	α	ω_{ln} (K)	λ_{ep}
1	0.01	7.271 (9)	823 (5)	0.505 (8)	1.983 (10)	102	1.046
2	0.1	7.263 (16)	823 (8)	0.513 (13)	1.947 (15)	115	0.97

11	0.99	7.267 (14)	841 (33)	0.534 (33)	1.872 (12)	163	0.807
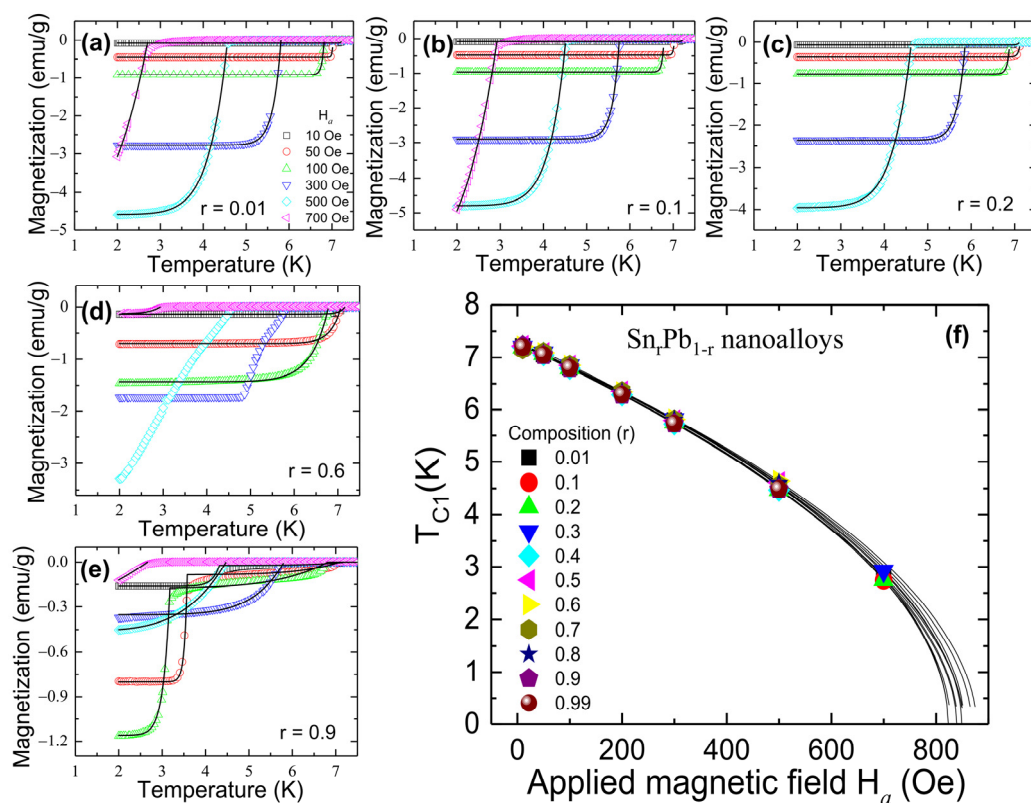

Figure 6. (**a**–**e**) the effect of applied field H_a on the transition temperature T_{C1} of Sn_rPb_{1-r} nanoalloys; (**f**) the H_a dependency of T_{C1}. The solid line is fitted to the expression given in the text.

Figure 7. Deviation of $H_C(T)/H_C(0)$ from the parabolic dependence of $1 - (T/T_{C1})^2$ fitted to the expression $H_C(T)/H_C(0) = [1 - (T/T_{C1})^\alpha]$, where α represents the coupling strength of the superconductor.

To investigate the effect of coupling strength on average logarithmic phonon energy ω_{ln} and the electron–phonon coupling constant λ_{ep}, we utilized the Eliashberg theory-based

McMillian formulation [34]. The corrections of the BCS values by strong electron–phonon interactions have been deduced in the following approximate analytic formulas that link $\omega_{\ln}/T_{C1}(0)$ to experimental thermodynamic quantities:

$$\alpha = \frac{\Delta(0)}{k_B T_{C1}(0)} = 1.764 \left[1 + 12.5(T_{C1}(0)/\omega_{\ln})^2 \times \ln(\omega_{\ln}/2T_{C1}(0))\right] \tag{6}$$

where $\Delta(0)$ is a superconducting energy gap [35]. Figure 8 displays a 2D plot of observed T_C versus estimated $\omega_{\ln}$ from Equation (6), where the green colors represent weak-coupled strength α. The value of $\omega_{\ln}$ is helpful for the description of the superconducting properties of conventional superconductors. The most weak-coupled $Sn_{0.9}Pb_{0.1}$ nanoalloy (sample #10) has α = 1.821(3) and $T_{C1}(0)$ = 7.272(3) K and shows the maximum phonon energy of $\omega_{\ln}$ = 241 K (phonon hardening). An electron–phonon coupling constant λ_{ep} can be estimated from the McMillan equation,

$$\frac{T_{C1}(0)}{\omega_{\ln}} = \frac{1}{1.2} exp\left[\frac{-1.04(1+\lambda_{ep})}{\lambda_{ep} - \mu^*(1+0.62\lambda_{ep})}\right] \tag{7}$$

where μ^* is the Coulomb pseudopotential described the Coulomb pseudopotential to represent the repulsive part of the pairing interaction and to estimate λ_{ep}; we set μ^* = 0.11 [34]. The obtained values of λ_{ep} are tabulated in Table 3. From calculated values of $\omega_{\ln}$ and λ_{ep}, it becomes clear that T_{C1} is a combined effect of both electron–phonon coupling strength and phonon energy. The minimum λ_{ep} = 0.685 and maximum $\omega_{\ln}$ = 241 K were observed for $Sn_{0.9}Pb_{0.1}$ bimetallic nanoalloy. The above value of λ_{ep} is smaller than that of pure Pb and Sn, λ_{ep} = 1.580 and 0.761, respectively. From the above finding, it is clear that the propagation of superconductivity through SPE weakened the electron–phonon coupling strength and hardened the phonon of the Pb phase.

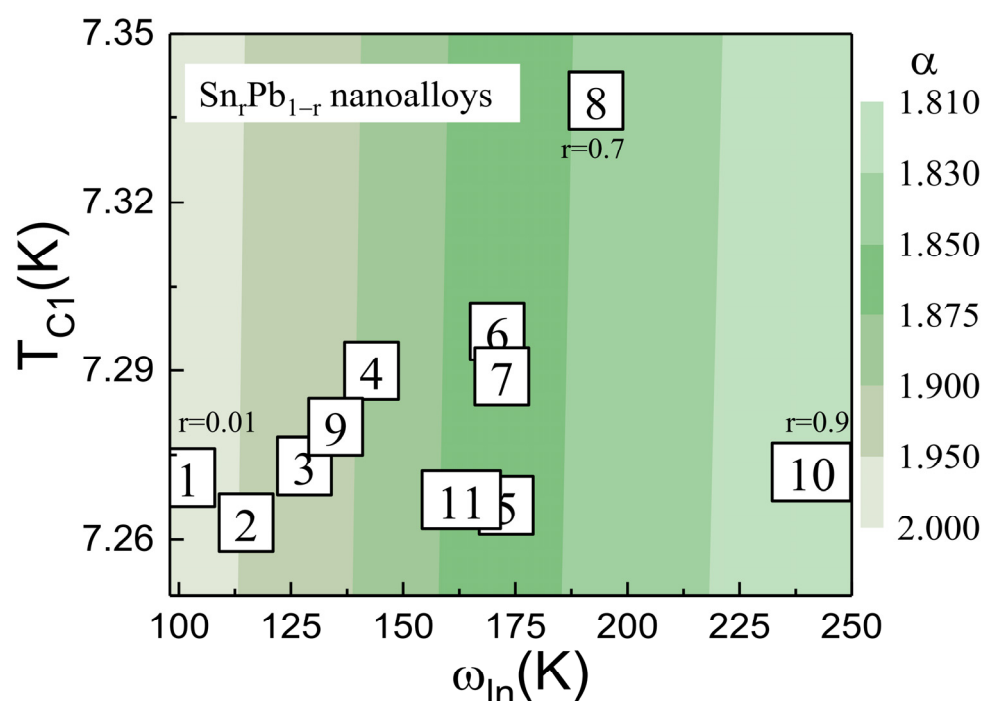

Figure 8. A 2D plot of observed T_C versus estimated $\omega_{\ln}$ from the equation explained in the text where the various green colors represent weak-coupled strength α, respectively.

4. Discussions

According to Pippard, Cooper pair size manifests as a superconducting energy gap $\Delta(0)$, which becomes shorter with increased coupling strength [36]. On the other hand,

phonon-mediated superconductors subversion of coupling strength was observed due to the phonon hardening effect. Therefore, the estimated values of GL coherence length $\xi_{GL}(0)$ and the average logarithmic phonon energy ω_{ln} are linked with the coupling strength of the superconductor. Figure 9 depicts the initial composition r dependence of calculated values of $\xi_{GL}(0)$ and ω_{ln} from Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) bimetallic nanoalloys. For an initial Sn concentration from r = 0.01 to 0.2, a steep drop behavior of $\xi_{GL}(0)$ was observed (the dashed red line is guided for the eyes), while the two elements of Pb and Sn form a solid solution of the α-Pb phase. The resultant phase diagram is thus completely different from those of other composition regions r = 0.2~0.99, typical immiscible bimetallic superconductors of Sn and Pb compounds, in which $\xi_{GL}(0)$ and ω_{ln} increase when Sn is substituted for Pb in the strong-coupled superconducting "parent" compounds. Notably, the solid solutions in the superconducting range exhibit $\xi_{GL}(0)$ anomalies at r = 0.01–0.1. The behavior is reminiscent of the disorder, and substitution in weak coupling superconductivity could enhance the electron–phonon coupling constant. A simplified physical model of electron–phonon coupling has been developed by Gao et al. to allow heat transfer from phonons to electrons and applied to study defects or disorders as a function of the strength of electron–phonon coupling [37]. The number of point defects produced in the primary damage state increases with the strength of electron–phonon coupling, signaling that the defect or disorder/substitution plays a role in the increasing strength of the electron–phonon coupling constant. A maximum of λ_{ep} = 1.046 from r = 0.01 and λ_{ep} = 0.97 from r = 0.1 (as shown in Table 3) indicates that the similarity suggests the enhancement of the electron–phonon coupling in the present case also has a substitutional origin. On the other hand, ω_{ln} shows a linear increasing behavior (the solid blue line is guided for eyes) with the decrease of coupling strength from r = 0.01 to 0.9, above which fluctuations were observed. The observed results agree with theoretical findings except for the high Pb concentration (r = 0.01 and 0.1) region.

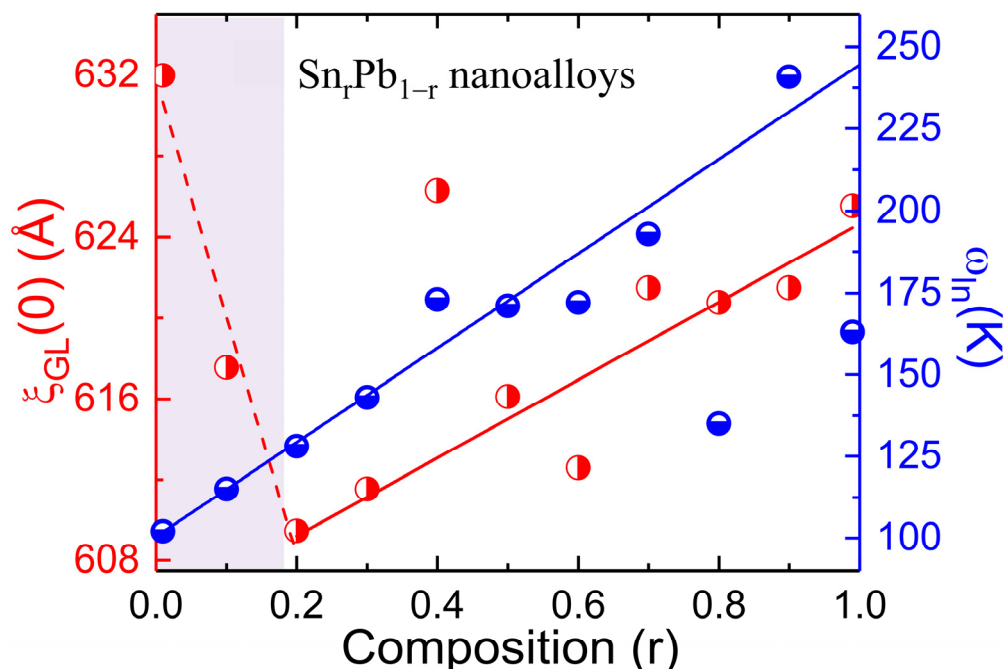

Figure 9. The plot of composition r depends on the GL coherence length and the phonon energy. The red dashed line and solid blue lines are guides for the eyes.

5. Conclusions

Sn_rPb_{1-r} ($0.01 \leq r \leq 0.99$) bimetallic nanoalloys were prepared using the simple physical annealing system. The observed discrepancy between the estimated atomic % using EDS and initial composition could be because of segregated grains of Sn and Pb. EDS-

mapped images show the inhomogeneous distribution of nano to micrometer size Sn and Pb segregated grains. SR-XRD refinement carried out using Rietveld analysis reveals the formation of the pure Pb-solid solution and immiscible mixed-phase nanoalloys. The effect of strain was observed on the lattice constants of Sn and Pb phases in all immiscible nanoalloys. Magnetization measurements revealed slight enhancement in the superconducting transition T_C for strained nanoalloy when fitted to modify the London equation. The coupling strength α, electron–phonon coupling constant λ_{ep}, and average logarithmic phonon energy ω_{ln} were estimated for all nanoalloys using the α-model and McMillian formulation. The estimate α, λ_{ep} showed subverted behavior and phonon hardening due to the propagation of SPE through the Sn matrix. The estimated sizes of the Sn phase increased from 50~60 nm as the composition r increased from 0.2~0.9, reflecting the excess surface contributions of the Sn matrix giving rise to enhanced propagation of SPE. In the immiscible regime, the behavior of $\xi_{GL}(0)$ is the same as that of the phonon energy, ω_{ln}, i.e., both physical parameters increase with the decrease of coupling strength α, revealing a superconducting proximity effect between immiscible Sn and Pb granules in the range of r = 0.2~0.9.
