Abstract: Online advertising is a marketing approach that uses numerous online channels to target potential customers for businesses, brands, and organizations. One of the most serious threats in today's marketing industry is the widespread attack known as click fraud. Traffic statistics for online advertisements are artificially inflated in click fraud. Typical pay-per-click advertisements charge a fee for each click, assuming that a potential customer was drawn to the ad. Click fraud attackers create the illusion that a significant number of possible customers have clicked on an advertiser's link by an automated script, a computer program, or a human. Nevertheless, advertisers are unlikely to profit from these clicks. Fraudulent clicks may be involved to boost the revenues of an ad hosting site or to spoil an advertiser's budget. Several notable attempts to detect and prevent this form of fraud have been undertaken. This study examined all methods developed and published in the previous 10 years that primarily used artificial intelligence (AI), including machine learning (ML) and deep learning (DL), for the detection and prevention of click fraud. Features that served as input to train models for classifying ad clicks as benign or fraudulent, as well as those that were deemed obvious and with critical evidence of click fraud, were identified, and investigated. Corresponding insights and recommendations regarding click fraud detection using AI approaches were provided.

Keywords: click fraud; artificial intelligence; machine learning; deep learning; click fraud detection features

1. Introduction

Advertising campaigns on websites and smartphone applications are examples of web services that have become common in people's lives. Campaign providers follow the pay-per-click (PPC) model, which charges advertisers for each click on an ad link. The PPC model is one of the fundamental approaches for funding and supporting websites. Advertising campaigns aim to publish ads on relevant web pages in order to increase profit; clicks on these ads may be natural and innocent from web users, but they may also be malicious clicks made by humans or automated software developed by competitors for fraudulent purposes, such as profiting from an organization or charging high fees from advertisers. According to Google Adwords statistics, the average cost of a click for Google Ads is \$0.89, and Google earned \$209.49 billion from advertising in 2021 [1].

With the growing number and diversity of malicious bots that exploit fraudulent autoclicks, much research has explored this topic and attempted to identify and predict whether fraudulent clicks are made. Throughout the past few years, artificial intelligence (AI) techniques have become increasingly prevalent in cyber security, efficiently contributing to detect and prevent a broad range of threats and attacks [2–5]. Various AI models are used to detect click fraud and assess whether a click is legitimate or illegitimate when a user or computer program clicks on an ad. However, despite advertisers' efforts to stop fraud, recent statistics reveal that the problem of click fraud is widespread and is predicted

According to the latest figures, the total cost for advertisers of fraudulent clicks reached around \$42 billion in 2021, with click fraud affecting 90% of PPC ad campaigns [6]. With the development of botnets that leverage fraudulent clicks, this issue must be investigated in depth in order to address it.

In this study, all solutions developed and published in the last 10 years that mainly use AI, including machine learning (ML) and deep learning (DL), for the detection and prevention of click fraud were examined. Various models and systems for PPC identification (benign or fraudulent) have been developed using different models. In this study, we also determined the features that were used as input to train models for classifying clicks, as well as which features were considered explicit and crucial indicators of click fraud.

The remainder of this paper is organized as follows. A background on ad clicks and click fraud is presented in Section 2. Related work on AI-based click fraud detection approaches is reviewed in Section 3. Commonly used public datasets in the field of click fraud detection are discussed in Section 4. The features used, and the most essential indicators for identifying click fraud are presented in Section 5, and the study recommendations are provided in Section 6. Finally, Section 7 concludes the study.

2. Background

2.1. E-Commerce

Electronic commerce, or e-commerce, is an electronic mode of business in which the selling and buying of products or services happen over the Internet [7]. This mode of business also allows for the transfer of funds and data using the Internet. According to Khan [7], e-commerce is a business transaction that happens over public electronic networks or the Internet. There has been widespread use of e-commerce in the last two decades, but it boomed particularly during the COVID-19 pandemic. E-commerce accounted for a total of 5% of retail sales before the pandemic. By the start of 2020, e-commerce accounted for 16% of overall retail sales, and this value continues to increase [8].

E-commerce offers business-to-business, consumer-to-consumer, and business-to-consumer business opportunities. A typical e-commerce framework works in the following ways:

- Businesses look for suitable online advertisers to advertise their brands, products, and services;
- Online advertisers, in conjunction with online advertisement providers, place the online ads of the business over the Internet;
- Providers then run different ad campaigns to target the end users of the products and services advertised by businesses;
- By following the links of businesses and companies provided in ad campaigns, users can browse the e-stores of these businesses and companies to purchase their products and services.

This is how e-commerce plays an important role in the growth of businesses. With the help of e-commerce, businesses can target their customers beyond geographic limitations, which is nearly impossible without e-commerce. Online advertisements are critical components of e-commerce. They can help businesses reach their customers [9].

2.2. Online Advertising Architecture

Online advertisement is a marketing strategy that aims to target potential customers for businesses, brands, and companies over various online platforms, such as social media [10]. A typical online advertising architecture comprises the following components:

2.2.1. Advertiser

An online advertiser is an entity that uses website content and online ads for marketing purposes. The tasks of an online advertiser vary according to client requirements. However, the primary roles and responsibilities of an online advertiser include creating content and enhancing users' interactions with the company or brand using various social media platforms and search engine optimization [10].

2.2.2. Publisher/Provider

Online advertising controllers or providers are entities that provide pathways for companies to advertise their products and services [11]. They are often called digital marketing agencies. Google AdSense, Media.net, Advertising.com, and Propeller Ads are some of the most common online advertising controllers or providers.

2.2.3. Advertising Campaigns

An advertising campaign is a series of advertisements that are designed to target a specified audience at specific times and locations in order to promote brand awareness, improve sales, and so on. Advertising campaigns carried out on various online platforms, such as Google, Facebook, and Twitter, are called online advertising campaigns. According to [12], these campaigns are crucial for successful e-commerce strategies.

2.2.4. Ad Networks

Ad networks are interconnections between businesses and companies that are willing to advertise their brands, products, and services with online platforms that are ready to host these ads. One of the most promising features of ad networks is that they collect ad space and match it to advertisers' requirements [13].

2.2.5. Users

Users are the target of advertisers. Advertisers target specific communities of users to grow their awareness of particular brands, businesses, products, and services. Online advertisers use different strategies, often equipped with advanced AI and ML algorithms, to target the most relevant and accurate group of users who can positively contribute to the growth of a business [14]. For example, if a particular user searches for smartwatches on Facebook, the Facebook ad campaign will show them ads related to smart watches after analyzing the user's interests.

2.2.6. Attackers

Attackers are adversary entities with the primary aim of harming online advertisers, businesses, and users. They can perform various attacks, such as man-in-the-middle attacks, distributed denial of services, information theft, and backdoor access attacks. The motivations of attackers can be either the financial or reputational loss of businesses or online advertisers [15].

Figure 1 demonstrate the high-level architecture of online advertising, which carried out in the following order:

- Service request: Initially, when a user requests a service offered by a publisher (1), the publisher receives it immediately;
- Service response: Upon receiving that request, it returns the original content/service requested (2);
- Ad request: Moreover, it asks the ad network to present the user with ads that match their query and profile as results for their search (3);
- (4) Ad matching: In the real-time auction that takes place on the ad exchange, the ad network uses profile information to determine which ads will generate the most revenue;
- Ad redirects: Upon selecting an advertisement or series of advertisements, the ad network directs the provided information to the user, who then instructed by the provider to fetches the ads (5–6);
- Ad fetching and retrieval: A final step is for the user to select, fetch (7), retrieve (8) the advertisement they wish to view.

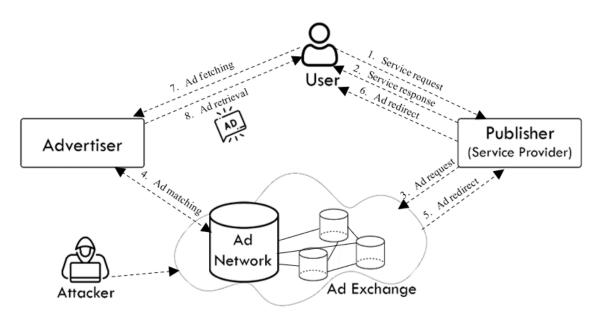

Figure 1. High-level architecture of online advertising.

2.3. Typical Online Advertising Services

Services that advertise businesses online are called online advertising services. They use social media platforms and search engines. The range of typical online advertising services covers the PPC model to social media and programmatic advertising services [16]. The creation of ads, the management of ads, and performance reporting are some of the common functionalities included in online advertising services. They have variable price ranges depending on several factors, such as the business industry, ad agency, and ad network [17]. Some common online advertising services include the following:

- PPC;
- Programmatic advertising services;
- Social media advertising services.

2.3.1. Pay-per-Click Advertising Services

In PPC, marketers place bids on phrases and keywords that can be used to trigger their advertisements. Thus, PPC is a paid advertising service. The optimization of PPC is a good option for marketers who want rapid qualified traffic to their online stores or sites [18]. This is because PPC starts giving results soon after an ad goes live. A common example of a PPC advertising service is search engine advertising.

2.3.2. Programmatic Advertising Services

Programmatic advertising services display ads to users on the basis of their interests [19]. This advertising service is automated. It learns the online behavior of users to display ads of targeted items that are of interest to them. Therefore, programmatic advertising services are sometimes called online behavioral advertising [20]. This type of advertising service can target individual users and seems to be a perfect marketing tool for marketers.

2.3.3. Social Media Advertising Services

Social media advertising services are a great way to build an interactive relationship with users who have an active presence on social media platforms. The use of social media sites, such as Instagram and Facebook, continues to increase [21]. Therefore, social media platforms are attractive markets for advertisers. Most social media platforms, such as Facebook, YouTube, and Instagram, have introduced their own advertising services.

2.4. Online Advertising and Fraud

Online advertising fraud is a false representation of the number of times a digital advertisement is clicked on or displayed [22]. This has an impact on online advertising campaigns because they are designed to show information about a product or service to only those people who are most likely to want it. In exchange, the publisher receives an advertising fee, and the advertiser's revenue increases. Competitors or dishonest publishers frequently engage in digital/online ad fraud by using automated bot traffic to click on advertisements repeatedly. In this case, the advertiser pays the publisher and the advertising platform, so this practice has the potential to scam a company with substantial amounts of money.

Many websites depend on advertising sales to make money, and many other businesses spend much money on marketing initiatives in an effort to boost sales [13]. The system relies heavily on automated exchanges that pair advertisements with potential clients. These automated procedures are used by digital ad fraudsters, who pose as real users and steal money by showing advertisements to fictitious consumers; this is how both advertisers and publishers are impacted by scams or fraud.

2.4.1. Click Fraud

For most businesses, digital marketing—and PPC in general—has replaced traditional forms of promotion. From small businesses to multinational corporations, everyone can benefit from having access to a broad market online. Roughly four billion individuals who use the Internet every day make purchases, so a well-targeted PPC campaign can mean the difference between drowning and swimming [23]. Five billion searches are made on Google every day, indicating the significance of PPC advertising; this enormous amount of traffic and the money involved make it an ideal target for fraud. Furthermore, click fraud has surpassed credit card fraud as the most expensive type of fraud performed annually.

The issue of fraudulent ad clicks is serious, especially when we consider that the cost of some keywords in Google Ads can be as much as \$50 or over \$100 per click [24]. In fact, the volume of click fraud can soon cause issues for the average advertiser, even with clicks costing around \$1 each. In 2017, one in five clicks on a PPC ad campaign was thought to be false in some way [25]. In the intervening years, both the methods and the scale of Internet fraud have evolved significantly.

2.4.2. Source of Click Fraud

Large-scale click fraud is frequently automated using a bot or another computer that copies a real person visiting a website. The bot continually clicks on an advertisement in an effort to fool a platform into believing that it is a person who wants to buy whatever the advertisement is selling [26]. Large numbers of clicks coming from one computer are likely to be noticed by a click fraud victim, and advertising networks and advertisers may also find this traffic suspicious. However, fraudsters can circumvent this by using a virtual private network (VPN) to route bot communication across a variety of constantly changing Internet protocol (IP) addresses. Additionally, they can engage in click fraud by using numerous computers in various locations, which are the main sources of high-, medium-, or low-volume clicks [27].

3. Literature Review

Along with other notable existing solutions for detecting click fraud, previous efforts have specifically used AI-based techniques, such as ML and DL. The purpose of these is to protect advertisers from being charged with fraudulent click expenses that cost them significantly and thus affect the quality of their ad campaigns. Previous findings have shown that the application of AI techniques to identify legitimate and illegitimate ad clicks yields good results, so they are deployed on both server and user sides to detect and avoid fraudulent clicks. In this section, we review previous studies conducted to detect and prevent click fraud. Our review is based on the following criteria:

- Case studies that leveraged AI techniques, including ML and DL;
- Studies that investigated the detection of click fraud in the advertising industry (There are several types of fraud that harm the advertising industry, including impressions fraud, publisher fraud, and click fraud. We will mainly examine studies on click fraud);
- Conducted in the last 10 years (2012–2022);
- Written in English.

The taxonomy followed in this paper is illustrated in Figure 2.

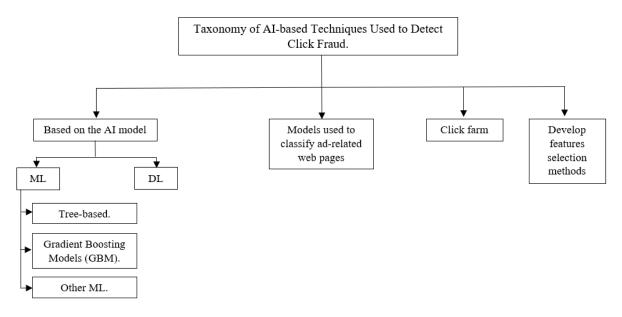

Figure 2. Taxonomy of the Literature Review.

3.1. ML-Based Click Fraud Detection Techniques

3.1.1. Tree-Based Techniques

To determine the source of a click, most previous solutions relied on ML techniques. There were many tree-based models that performed extremely well. Traditional tree-based models can be either Decision Trees (DT) or Random Forests (RF) or Extremely Randomized Trees (ERT), etc. The former can be used to build all tree-node models, while the two latter builds many decision trees in parallel by impling different strategies. Moreover, other versions of tree-based approaches have been employed as well.

Li et al. [28] developed the MadTracer system, which considers ad infrastructure and involves many ad-related parties, such as ad delivery paths and ad context. The system detected a number of attacks, which were later classified as drive-by download, scam, and click fraud, by using detection rules based on a DT classifier. A previously unknown type of click fraud was observed (by Google Safe Browsing and Microsoft Forefront combined)-a fake ad click that leads the visitor to a landing page without the user seeing or clicking on the ad. MadTracer which is a browser-based solution uses knowledge about harmful ad paths and the behavioral features associated with them to activate an alarm and detect when a user reaches a suspect ad path. Berrar [29] used Random Forests (RFs) with skewed bootstrap sampling to determine a publisher's status (fraudulent vs. legal) based on clicks associated with its ad campaigns. Additional features, such as the click profile (the time gap between subsequent clicks), were extracted and were available in two stages: (1) long click profile and (2) short click profile; clicks made with the same IP and URL were also investigated. Two tests were carried out to assess the usefulness of the provided features; the first model contained the raw features in the dataset and the long click profile, whereas the second model included the short click and URL profiles. With an average accuracy of

49.99%, the first model performed best in the validation set, and in the test set, it had an accuracy of 42.01%. Yan and Jiang [30] conducted a study to determine suitable classifier models for detecting click fraud in commercial and advertising logs. Several classifiers were trained using numerical features, such as IP and the number of clicks at different time intervals during the day, as well as statistical features, such as the standard deviations of clicks in various periods (morning, night, etc.); RFs, Bayesian networks (BNs), decision tables, REPTree, and naive Bayes (NB) were then used to classify clicks. The MapReduce paradigm was applied to develop the preprocessing and feature extraction modules, and the findings showed that tree-based approaches outperformed the Bayes approach because of the imbalanced distribution of fraudulent versus valid clicks (the majority class). In a study by Perera et al. [31], a novel ensemble model was introduced based on user behavior from click patterns, and valuable new features derived from raw ones that could not be used in their original forms to detect click fraud, such as 20 features derived from time at (i.e., average, max, variance, and skewness), were calculated for clicks across various time intervals. Several classifiers were attempted to build an ensemble model that includes the six best-performing classifiers: bagging with J48, bagging with repetition tree (REPTree), bagging with RF, MetaCost with J48, LogiBoost with J48, and random subspace with J48; these proved successful on validation and test sets and demonstrated their generalizability with an accuracy of 59.39%. Oentaryo and Lim [32] focused on extracting various types of features, including basic features, such as publisher account and click-per-ad ratio, as well as spatial features, such as click fraction of the top 20 countries, as input when training ML models, such a Logistic Regression (LR) and extremely randomized trees. Overall, the findings indicated that temporal (time series) and spatial (clicks from specific risky countries) features are effective fraud markers, and ensemble methods provide beneficial solutions to highly unbalanced classification tasks with varied attribute values and noisy/missing patterns. Perera [33] indicated that understanding click patterns would greatly aid in the challenging task of detecting and preventing fraudulent clicks. Support vector machines (SVMs), LR, BNs, multilayer perceptron (MLP), and several DT algorithms, including C4.5, REPTree, and RF, were used. Under-sampling was also applied to overcome the problem of dataset imbalance, in which majority class records are used with all minority class records. Addresses, bank accounts, and other features unrelated to publisher or click behavior were excluded. A number of fraud detection features used in Google's fraud detection system, as well as most fraud detection mechanisms applied to PPC ads, were considered to extract useful information. Feature selection (FS) techniques were ignored because using all features resulted in the highest accuracy. It was found that using ensemble and sampling techniques separately does not achieve good results; however, when these techniques were combined, performance improved significantly. Bagging with C4.5 + cluster-based sampling was selected as the final model. The author stated that temporal features (e.g., the click ratio in 5 min intervals) and spatial features are critical indicators of fraud detection. Oentaryo et al. [34] discussed the top five entries (for the top five teams) in a click fraud detection competition using the FDMA 2012 dataset, including what we reviewed earlier in [26,28,29,32,35]. One of the teams pointed out that to identify multiple fraud patterns, they must first extract the publisher's characteristics from a variety of statistics, such as mean, standard deviation, and count, and then use single ML models, such as the Functional Trees and Reduced Error Pruning Tree (REP tree), as well as ensemble models, such as RF and rotation forest. However, the ensemble of ensemble models achieved the highest accuracy at 52.3%. Xu et al. [36] presented an interesting method for distinguishing between human and bot clicks, which included checking whether the user's browser supported JavaScript and the tracking and monitoring of mouse movement. If there is mouse movement and JavaScript support, they are real users (and several functionality tests will be performed to validate this); otherwise, they are bots. The authors also evaluated clicks from suspicious websites and IP addresses listed on blacklists, along with the user's browsing behavior, as important indicators for detecting bot clicks. On the advertiser's side, the C4.5 model was used to classify and

evaluate clicks in real time for a 10-day campaign, achieving an impressive accuracy of 99.1%. He et al. [37] reported that selecting the right features and models is essential for the efficient detection of click fraud. They built a solid model by combining DTs and LR. These features were divided into two categories: historical and contextual. The latter included features such as the device used and the page on which the advertisement was displayed, whereas the former included data related to the user's behavior and interactions with the advertisement, such as the CTR in the previous week. Contextual features are especially important to new users or ads, but historical features play a more significant role and provide a more detailed description of click identification. The results showed that as the time difference between the training and test sets increased (weekly training and evaluation), the prediction accuracy decreased, whereas it increased with daily training and testing. Ravi [38] investigated touch fraud in mobile gaming apps by using the C4.5 model to classify ads that are tapped or pressed without the user's knowledge and that are uninteresting to them. In terms of features, the app's features, such as app ID, release date, current version, and rating, were extracted, as well as the app developer's features, such as the number of apps developed and the ratings of these apps. The author also introduced a new set of features related to ad control location-based features, which included observing ad constraints in the apps and verifying their implementation in each app. For example, there is a constraint state in which the number of ads on a mobile screen should not exceed one ad, and there is a need to ensure the visibility of the ad so that it is not hidden behind a button, an image, or other similar objects. Violation of these constraints will almost certainly result in touch fraud. The proposed features improved the classifier's performance across all metrics. Beránek et al. [39] used ML techniques, including NBs, DTs, and SVMs, in their work. They analyzed click time from the available features in the dataset and extracted multiple comprehensive features from it, such as time of day, period of day, and type of day. These features were then combined into a timeprint. They ran several experiments to evaluate how accurate a user's timeprint was in modeling the behavior of the user for the purpose of identifying click fraud. The results demonstrate that the timeprint is an effective solution for enhancing the quality of click fraud detection and that the proposed approach may be used as a pre-processing step. Berrar [40] conducted experiments using the FDMA2012 dataset and developed a model to detect suspicious publishers and clicks. In the RF approach, the average precision of the final ensemble model on the blinded test set was 36.20%. The experiments also revealed that features relating to click time might provide the most useful evidence concerning fraudulent activities. Guo et al. [41] claimed that most false clicks come from malicious data centers and that bots are designed for this fraudulent purpose in such centers, which are called CloudBot. A traffic-based near real-time approach was developed using ML techniques. As raw traffic was used at first instead of logs, logbased sampling and partitioning methods were inapplicable; therefore, a novel approach, IP-based sample partitioning, was proposed in which traffic flow data are sampled based on a user's IP address by hour. To maintain user privacy, the construction model did not include any information from the application layer; instead, most of the features were from the transport layer, such as the maximum segment size and time to live, in addition to statistical traffic features, such as packet variance in each flow. The study's findings demonstrated that the proposed system could spot click fraud while preserving privacy and that tree-based models achieve effective performance. Lia and Jia [42] evaluated the effectiveness of the RF algorithm in spotting fraudulent clicks using an ad click dataset, which needed to address imbalance; the purpose was to minimize information loss caused by undersampling or overfitting because of oversampling. As a result, the following approach was used: oversampling positive samples and undersampling negative samples. Following an analysis of the raw features in the dataset, more than 100 features were calculated, derived, and used as input to the RF, which was then compared with the SVM, NB, and DT, with an accuracy of 93% for predicting positive samples (i.e., legitimate clicks) and 91% for predicting negative samples (i.e., illegal clicks).

3.1.2. Gradient Boosting Models (GBM) Techniques

GBM and its variants, on the other hand, have been widely employed in previous studies due to their effectiveness in extracting both feature extraction and click classification. Gradient boosting models are an ensemble method that builds many decision trees sequentially. The extreme gradient boosting (XGBoost) variant is a more regularized version of Gradient Boosting.

Using generalized boosted regression models, Phua et al. [35] found that fraudulent clicks exhibit distinct spatio-temporal patterns. The authors emphasized that adopting simple statistical methods to extract features related to click behavior, click frequency, and high-risk click behavior would significantly increase model performance and reduce the overfitting of training data. Wang et al. [43] proposed a framework that combines two modules of supervised learning with rule-based statistical methods to deal with click fraud issues in both the user and traffic layers, as well as to identify as many click patterns as possible. Once the model is applied in both layers, users and their clicks are classified in the user layer, and fraud traffic is identified directly in the traffic layer. The outcomes show that when the gradient boosting decision tree (GBDT) classifier is trained with the derived hybrid features, such as time-related features (e.g., frequency of the cookie and IP recurrence feature), in a certain time window, there is an effective improvement in performance. Jianyu et al. [44] took the first step in detecting fraudulent activity in huge advertising platforms. Because nominal characteristics made up over half of the features in their dataset, they developed a unique coding method to convert nominal attributes to numeric ones while preserving the most useful information for fraud detection. They thoroughly examined features and determined the key features (i.e., if a feature with its frequency can identify more than 50% of the fraud activity in a dataset, it is a key feature). Furthermore, the key feature is combined with its frequency and stored in the dataset as a new nominal feature. Finally, to classify clicks in online advertising platforms, they constructed ML models, including LR, DT, GBDT, and XGBoost. In their study, Minastireanu and Mesnita [45] used a state-of-the-art ML algorithm, the light gradient boosting (LightGBM) decision tree-type approach, to explore the journeys of visitors who regularly click on ads but do not download apps (referenced in the ad link). As they engineered the features, they extracted time-related features from click time and calculated additional features, such as count (grouped by multiple features) and group-by-count unique values. They confirmed that the chosen algorithm outperforms XGBoost and stochastic gradient boosting (GB) in terms of computational speed and memory consumption; the outcomes of their experiments illustrated the effectiveness of the proposed method, achieving an accuracy of 98%. The vast number of raw click data, complexity, high cardinality, and unbalanced class distribution, according to Singh and Sisodia [46], are some of the obstacles that make click fraud in the advertising industry crucial. This issue requires the use of a cautious algorithm. Therefore, they used the gradient tree boosting (GTB) model, which has been evaluated on multiple datasets and compared against 11 other ML algorithms; it demonstrated usefulness in detecting fraudulent publishers and overcoming the stated challenges. To investigate the behavior of users who repeatedly click on an ad without performing the required action (e.g., download an app or make a specific purchase), Dash and Pal [47] conducted a study to develop a robust, adaptive, and scalable feature set for click fraud detection. They trained models, including SVM, KNN, DT, RF, and GBDT, with input features, such as URL, ad server IP address, and referrer URL. Nevertheless, there were some limitations in this study because the authors anticipated more detailed features, such as those explaining information about the user (e.g., geographical region), as well as features describing click behavior, such as mouse movement patterns; in addition, detailed click time features, such as day, hour, and minute, cannot be extracted. The GBDT method achieved an accuracy of 97.20%. Viruthika et al. [48] constructed a model based on the XGBoost method, which is commonly used in both the feature extraction and feature selection (FS) stages. The method demonstrated effective performance compared with other classification algorithms after the completion of multiple massive trials and testing. This study included the main

features of click time, IP, app, OS, and device, which may be gathered from each click to train the model. The method achieved 91% accuracy, effectively handled missing data, and prevented overfitting. This is because it is preferable for the click fraud detection system to be optimized at a low cost while maintaining good precision and recall scores. Srivastava [49] developed an approach based on ML and heuristics. First, to select the features of interest to include in the model, the relationship of conversions (i.e., the action computed when a visitor interacts with an ad) with each feature (e.g., IP, app, and device) was analyzed. For example, the authors demonstrated that the relationship between click and rate conversions for benign clicks is that the latter drops significantly as the former increases because a legitimate user is likely to click on the ad several times but will only perform specific actions (e.g., download an app) once. The study's key objective was to exploit a minimal feature set with high accuracy and efficiency by applying the following models: linear support vector classifier (SVC), GB model, KNN, MLP, and NB. Furthermore, the categorical features were converted into one hot encoding to enhance effectiveness. Thejas et al. [50] developed the cascaded forest and XGBoost classifier (CFXGB) model, which is based on a combination of the cascaded forest to handle the original dataset with additional features and then XGBoost for classification. Their results showed that it is a feasible method for detecting click fraud. Experiments were carried out on three widely known public datasets: TalkingData, Avazu, and Kad. In all these datasets, click time was split into month, day, and hour, with certain features that had nothing to do with identifying the click excluded. Finally, meta-analytical comparisons with previous studies that used ensemble models, such as RF and GBDT, revealed that the proposed method is more effective in terms of performance than the other models. Gohil and Meniya [51] explored the capability of the XGBoost classifier to recognize malicious click cases as a feasible solution. After execution, the model was verified to be highly successful without diminishing the final accuracy; in addition to the existing features of the datasets, the time-to-click feature was split into month, day, and hour, and the IP feature was paired with all other features. When classifying clicks in the first dataset, XGBoost obtained a high accuracy of 96%. A further study by Singh and Sisodia [52] found that transferring from appropriate learning domains to new ones can improve model performance while saving training time. Their approach focused on the integration of 1D user click time-series non-image features into a 2D graphical image. Next, classification was performed using five main ML models: SVM, RF, DT, AdaBoost, and GBT. The latter demonstrated effective performance, with 79.8% precision.

3.1.3. Other ML Techniques

Moreover, there are other ML models that can be exploited in order to effectively perform the click classification.

Gabryel [53] deployed JavaScript on an advertiser's site for a month to gather all accessible click data and determine the origin of clicks (humans or bots). He developed an analytical approach that uses the term frequency-inverse document frequency (TF-IDF) algorithm, weights all features, and then leverages the KNN model to distinguish benign or fraudulent clicks. Compared to using only the TF-IDF technique, assigning weights to each feature enhanced the classification results. In a two-stage model, Almahmoud et al. [54] used two types of fingerprints: one rule-based fingerprint and one ML-based fingerprint. When a user requests a web page, in the first stage, the fingerprint is retrieved from deterministic information about the user and web page navigation, whereas the other fingerprint is generated in the second stage by using the features of the click behavioral patterns during and after clicking on the ad and then classifying the click as legitimate or benign. Several classifiers have been examined, but the KNN classifier has proven to be the most accurate, with a precision of 97.6%. Pan et al. [55] exploited top-rank-k frequent pattern mining in combination with an SVM classifier to improve the effectiveness and coverage of click fraud detection. The proposed method depends on click abstraction, click frequency description, and other aspects regarding the ad click. A simulation was carried

out in a practical setting to assess the efficiency of the method, and the results showed that it is useful and efficient, as it considerably decreases time complexity. To effectively handle imbalanced datasets, which are common in click fraud detection data, causing the classifier to be used to be either overfitted or underfitted, scholars have developed several resampling techniques to address this issue. According to Thejas et al. [56] developed an algorithm with the goal of modeling temporal click fraud data in terms of probabilities, which takes into consideration time scales of minutes, hours, and seconds. This algorithm can predict click fraud behavior in these scales. The auto-regression and moving average models were constructed, and they used only time-series features and labels/classes (fraud/benign) without requiring a huge number of features to be involved; subsequently, the LR classifier was applied to differentiate between fraud and legitimate clicks. Borgi et al. [57] tested the extent to which extraordinary timeprints can be indicators of click fraud detection. The proposed rule-based method used offline rules, such as the blacklist rule, which recognizes fraud by considering the time spent by the human/bot to click on the ad, and then goes through the classification using the LR classifier. This model considers an important aspect that the authors believe is the most crucial predictor of whether a click is fraudulent: measuring the amount of time a person spent surfing the Internet prior to clicking on the ad. The study concluded that timeprints might be significant indicators of false clicks. Li et al. [58] established the first model to detect click fraud using multimodal and contrastive learning approaches, taking into consideration the variations in demographic information, behavior patterns, devices, and media used by actual users and fraudsters while clicking on ads. The MCCF model was developed based on the use of three modules: wide and deep features, behavior sequences, and heterogeneous networks. It required integrating multimodal information into each layer of the MLP and then using contrastive learning during the model training phase to overcome the imbalance problem. Several attempts have been made to test the proposed model in varied forms, such as model validation after eliminating wide and deep features and after excluding the behavior sequences. The three-component MCCF demonstrated its efficiency by achieving the greatest performance and surpassing all preceding models by a significant margin at 98.7% precision. Aberathne and Walgampaya [59] devised a framework known as the real-time mobile ad investigator. The system is knowledgeable and capable of detecting fraudulent clicks using an all-new supervised ML model known as the hidden Markov scoring model (HMSM), which was developed by combining the hidden Markov model, a rule engine, and pattern recognition algorithms. The entropy-based binning approach was also used to extract and transform new categorical features. The HMSM classifier was beneficial as a supervisor learning method; with an accuracy of 94%, it minimized complexity during training while performing well while classifying blind data. The findings showed that the model is effective in detecting fraud not only in clicks but also in impressions and user sessions in the field of advertising. Mikkili and Sodagudi [60] used a dataset along with its raw features to calculate the number of clicks on the same ad per day, as well as the frequency of each click because, as the authors noted, these are vital indicators to determine where legitimate and illegitimate clicks originate. The proposed method for detecting invalid clicks, which result in significant illegal gains, depends on the usage of two classifiers, LR and Gaussian naive Bayes (GNB), which obtained exceptional accuracy of 99.23% and 99.78%, respectively. Dekou et al. [61] highlighted a recurring issue with detecting fraud in e-commerce—datasets are commonly very imbalanced, and fraudulent humans or bots constantly adapt their behavior to remain undetected. The model used depends on the powerful open-source libraries H2O and Catboost (a GB technique for DT libraries), as well as AutoML, which attempts to collect numerous basic models in order to enhance prediction quality and produce a more efficient aggregation model. It was notable that the ensemble models outperformed the individual models, with the stacked ensemble model achieving the greatest performance with an area under the curve metric of 98.85%. Singh and Sisodia [62] developed a method called the quad division prototype selection-based K-nearest neighbor classifier (QDPSKNN) to handle the dataset

imbalance issue, with the objective of minimizing capacity requirements and enhancing execution performance. This process is based on dividing the data into four quarters and then performing undersampling. The performance and generalizability of the proposed method were evaluated using the FDMA2012 dataset of ad clicks, in which 103 features derived from previous work [35] and numerous trials on 15 other common imbalanced datasets were used, with the sizes and quantities of the features in the datasets varying. The approach was compared with the traditional KNN model. The results revealed that QDPSKNN enhanced classification and was successful in addressing data imbalance, as it gained the best accuracy in 13 out of 16 datasets and obtained a precision rate of 75.1% in the click-related dataset.

3.2. DL-Based Click Fraud Detection Techniques

Additionally, DL methods have been investigated in some studies as a solution for detecting click fraud. Either alone, or in combination with other ML techniques.

Mouawi et al. [63] developed the CFC click fraud detection model, which uses customdesigned features along with ML models, including KNN, artificial neural network (ANN), and SVM. The model distinguishes itself by allowing a third party to supervise and control the entire click fraud detection process through crowdsourcing ad requests, compared to usual models that place this task in the hands of an ad network or advertiser. The classifiers were evaluated with different kernels and values; the findings showed that KNN with K = 5 (number of neighbors) produces impressive outcomes, with an accuracy of 98.26%. The work of Renström and Holmsten [64] was one of the few that used unsupervised ML techniques in which they used autoencoders (AEs) because of a shortage of labeled data. The procedure was carried out in three steps. First, a simple three-layered AE was used; second, a stacked AE was proposed, which was simply a three-layered AE, but each layer was trained separately before each output served as an input to the subsequent classification model. Finally, a variational autoencoder (VAE) model was used, which operates similarly to the second model, but statistical approaches, such as mean, standard deviation, and latent vector, are applied. A click fraud dataset was one of the datasets used to evaluate the proposed models. The results revealed that when time- and date-related features are eliminated from the models, their performance suffers considerably, with the stacked model outperforming the others. In another investigation, Zhang et al. [65] developed a method called CSBPNN-ABC to detect fake clicks, and the findings were promising. They primarily applied the back propagation neural network (NN) technique, which they combined with the novel artificial bee colony (ABC). They used the ABC algorithm to find the optimal feature set, and then the CSBPNN-ABC approach was used to classify ad clicks across mobile platforms. Throughout the experiments, the authors found that the basic features included in the dataset are insufficient for the direct creation of the click fraud detection model. As a result, they relied on Oentaryo's [34] earlier work, in which he retrieved more than 100 features using statistical methods. Only 13 characteristics were used in the investigation to enhance performance and minimize training complexity. Compared to cutting-edge techniques on real-world click datasets, the proposed model performed effectively. According to Thejas et al. [66], there is a shortage of studies in the existing literature that determine and develop various techniques for detecting and preventing click fraud, notably because a bot can be an intelligent attacker that constantly learns from the classification training method in order to mislead the fraud detection model training process. As a result, the authors proposed a model that is a combination of an ANN and an AE. Furthermore, the dataset used is highly unbalanced, so a semi-supervised generative adversarial network was included as a solution to improve the accuracy of the ANN; the ANN contained several layers in which each layer learns the pattern and distribution of the click for a specific extent and then passes the understanding to the next layer and so on. The results showed that the method is effective for detecting fraud. However, because of a lack of illegitimate clicks, the AE was unable to recognize bot clicks that mimic the pattern or distribution of human clicks, and these illegitimate clicks were misclassified as benign. In 2020, Shi et al. [67] created ClickGuard, a mobile solution that leverages mobile sensors, such as an accelerometer and gyroscope, to enter signal-related data because the pattern of vibration signals differs greatly between legitimate click actions and fraud actions. Mel frequency cepstral coefficients were chosen to extract features and build strong features (e.g., formants of the signal spectrum) in order to distinguish fraudulent click signals, and then classify the data using classifiers, such as RF, logistic model tree, and convolutional neural networks (CNNs). The latter performed best, followed by the RF classifier. Hu et al. [68] introduced a hybrid model that combines a novel weighted heterogeneous graph and deep neural network (DNN). In the first phase, a weighted heterogeneous graph was established to display the behavioral patterns, apps, devices, and other characteristics of an advertisement's clickers. Then, the time was separated into numerous windows, and statistical methods were used to derive new features based on each window, with the log data for each app split into 24 parts every day (i.e., the time window was 1 h). Compared with other models, such as SVM, RF, and fully connected neural network (FCNN), the developed model performed excellently. Liu et al. [69] introduced a method to detect the distribution of fraudulent clicks among human clicks, in which they first used a priori probability. As the raw features in the dataset do not provide an overview of users' behavior when they click on an ad (as the authors stated), they relied on earlier features derived by Oentaryo [34]; they then calculated the entropy value to choose the new included features, transformed it into a feature matrix over many time windows, and then divided it into two primary windows with different temporal patterns. They also generated statistically new features from the given characteristics that were appropriate when used to train a cost-sensitive CNN method. To demonstrate the effectiveness of the proposed method's performance, they compared it with multiple ML models, such as J48, RF, and SVM; their algorithm outperformed the aforementioned models with a precision of 89%. Gabryel et al. [70] used FCNNs in an experiment to classify clicks as legitimate or illegitimate (click monitoring) and to examine visitors' behavior after clicking, such as whether they would fill out a form or purchase a specific service (lead monitoring). Commonly available data from the user's browser were collected, such as browser type, OS, number of page views, and mouse movement, to train the model. Three models were tested: an MLP network, a multilayer network model, and a particular neural network (NN) with one hidden layer in which the weights of the underlying layers were trained first. The last model had the most efficient performance, with 99.5% accuracy. Zhu et al. [71] focused on a type of click fraud known as a humanoid attack, in which human click behavior and click patterns are fully mimicked to dodge detection by earlier works. The authors developed the ClickScanner tool, which uses VAEs to detect the stated type of attack, along with establishing a data dependency graph using static analysis to extract the major features from mobile apps and generate a feature vector. Several features, such as ad view size, which the attacker can leverage to specify locations of the falsely clicked ad within the ad view, were considered to investigate malicious code pieces that an attacker can infuse into apps in order to produce false clicks with no user intervention. Compared with earlier tools, the proposed tool was capable of detecting 170 abnormal click behaviors from 166 suspect apps in less time. Chari et al. [72] conducted a study to evaluate many ML methods, including LR and recurrent NNs, and several boosting techniques, such as LightGBM, AdaBoost, and GB. In terms of feature engineering, new features were added, such as the frequency feature, which relates to the IP feature by calculating each unique IP in the dataset and its frequency, as well as adding the click ID, which is the identifier that reserves a certain number for each click. The time feature was divided into hour and day, and the IP feature was paired with all the other features in a combination of one/two attributes. With an accuracy of 98.69%, LR performs admirably; the findings demonstrated that using the LR algorithm to detect click fraud is quite successful and will attract the interest of advertisers and publishers.

3.3. Models Used to Classify Ad-Related Web Pages

There are studies that have also explored the use of AI models to classify pages with ads or not for fraud detection purposes. For example, Crussell et al. [73] conducted the first click fraud study on Android app ads, examining two basic behaviors: displaying ads while an app is running in the background and clicking on ads without any real interactions from the user. Moreover, they introduced a tool called MAdFraud that can work with multiple applications at the same time and directly recognize clicks and impressions through three stages: building Hypertext Transfer Protocol (HTTP) request trees, defining ad request pages using ML, and detecting clicks using heuristics in HTTP request trees. Several useful features for training the RF model were extracted in the first stage, such as request length, publisher ID, and timestamp. The results showed that there were 21 click fraud apps detected, with 35 clicks occurring in the background and 24 clicks occurring in the foreground. Also, in a study conducted by Iqbal et al. [74], a method called Fight Click Fraud (FCFraud) was proposed to provide a solution to click fraud and to safeguard users' devices from unintentionally becoming part of a fraudulent click network after being infected by malware. On the user's side, this solution could be integrated into the anti-malware software of the operating system (OS). In general, FCFraud recognizes background activities, scans and analyzes HTTP packets, and uses ML classifiers, such as NB, SVM, K-nearest neighbors (KNN), C4.5, and RF, to automatically identify ad HTTP requests. Following these, it applies a variety of heuristics to avoid false ad clicks.

3.4. Click Farm

Moreover, some studies have focused on a type of click fraud known as click farming—in which a large number of cheap laborers is hired to click on paid ad links.

Jiang et al. [75] used PU learning, a positive-unlabeled learning method, to gather reliable negative examples from an unlabeled set. They conducted weighted logistic regression to examine the contribution of extracted features in analyzing click farming on one of the largest Chinese shopping sites and to investigate whether click farming occurred in stores hosted on this platform. Among many classes, including SVM, RF, and NN, and then combining them through an ensembling method, the latter achieved the best accuracy at 97.4%.

3.5. Develop Feature Selection (FS) Methods

Furthermore, some authors have developed feature selection (FS) methods that have been validated primarily on datasets related to click fraud.

Taneja et al. [76] presented a novel method for selecting features using the recursive feature elimination method, classifying legitimate or illegitimate clicks related to mobile web browsing and dealing with data imbalance using the Hellinger distance decision tree (HDDT) classifier. Statistical methods were also used to engineer the features, such as click time, from which 12 features were extracted using statistical measures, such as maximum, average, and skewness. Experiments were carried out to compare the model with robust ML models, including J48, LogiBoost, REP tree, and RF; HDDT performed well, with an accuracy of 64.07%. In their further study of FS approaches, Thejas et al. [77] revealed that FS is beneficial for enhancing algorithm performance and lowering computing overhead; however, it does not demonstrate a meaningful benefit in some classifiers, such as RF classifiers. As a result, two FS techniques were designed: metric-ranked and accuracyranked feature inclusion. These two strategies are fundamentally hybrids of the wrapper and filter methods, with each feature assigned a value and then ranked, followed by the selection of features. The performance of the two techniques was validated using 12 datasets, three of which were related to click fraud. The proposed techniques do not require knowing the number of features in advance; they add features incrementally and do not require a specific, minimum, or maximum set of features. And lastly, Thejas et al. [78] designed the Kalman-SMOTE (KSMOTE) algorithm by combining the strong performance of the synthetic minority oversampling technique (SMOTE), an oversampling technique in which synthetic samples are produced for the minority class, along with a Kalman filter. The approach removes noisy samples in variable proportions based on the user-specified number of iterations, thus maintaining class balance. The RF model was then applied to evaluate the proposed algorithm's performance on three imbalanced ad click datasets. The KSMOTE outperformed earlier algorithms in most datasets, demonstrating a significant gain in performance.

As a summary of all previous reviewed articles, Table A1 in Appendix A displays the dataset, used features, strengths, limitations, outcomes, and evaluation metrics. Note: Studies are listed in chronological order (2012–2022).

4. Common Datasets in the Field of Click Fraud Detection Using AI Techniques

In this section, we go over the most relevant datasets mentioned in the literature review to detect and prevent ad click fraud using AI techniques. Private/non-open-source datasets, as well as those related to other fraud types, such as ad or impression fraud, are excluded. We discuss the descriptions, raw features, and some of the issues with the datasets, as identified in the literature review, as well as how these issues are addressed.

4.1. FDMA 2012 BuzzCity Dataset

4.1.1. Dataset Description

The FDMA BuzzCity dataset [79] was introduced in 2012. This dataset has been used in several experiments [26,28-32,35,37,39,43,59,62,66,73] and is divided into two portions—publishers and clicks—The publisher dataset contains data relevant to the publisher profile, whereas the click dataset provides click records associated with each publisher. All field descriptions for both datasets are shown in Section 4.1.2. This dataset was originally offered as part of a competition with the goal of developing an effective model/technology to detect fake publishers and understand publishers' lack of credibility patterns based on publishers' profiles and clickers' click behavior. Each publisher has three statuses: OK indicates that the publisher is benign, fraud denotes that the publisher is illegitimate (intentionally generates high-cost clicks with no real interest in the ads by using automated software or click farms), and observation indicates that the publisher's status has not been verified because the publisher is either new or has too many clicks but is not yet declared fraudulent. There are three sets of data available in FDMA 2012 BuzzCity: a training set (to develop predictive models), a validation set (to select models), and a test set (to test model generalizability). During a period of three days, the click dataset captures data related to clicks, while each publisher dataset records publishers who received at least one click. Table 1 presents the statistics of the dataset.

Table 1. Statistics of the FDMA 2012 BuzzCity dataset.

| | | | No. of Publishers | | | |
|------------|--------------------|---------------|-------------------|-------------|---------------|-------|
| Dataset | Time Period | No. of Clicks | Fraud | Observation | ОК | Total |
| Train | 9–11 Feb 2012 | 3,173,834 | 72 (2.34%) | 80 (2.60%) | 2929 (95.07%) | 3081 |
| Validation | 23–25 Feb 2012 | 2,689,005 | 85 (2.77%) | 84 (2.74%) | 2895 (94.48%) | 3064 |
| Test | 8–10 Mar 2012 | 2,598,815 | 82 (2.73%) | 71 (2.37%) | 2847 (94.90%) | 3000 |

4.1.2. Raw Features

As stated previously, the FDMA 2012 BuzzCity dataset has two sub-datasets. Because the data are obtained through mobile devices, certain features of similar data on desktop computer networks are not available. The publisher dataset contains information about the publisher, such as ID, address, bank account, and status, as listed in Table 2. The click dataset, on the other hand, contains information on the source of the click, such as ID and IP, as well as other attributes that describe the click behavior, such as device and click time, as shown in Table 3. For the sake of privacy protection, most of these data have been anonymized. The studies in the literature review did not use these features in their raw form to train models for detecting click fraud but instead went through a series of

processes with the purpose of engineering features using statistical approaches, a collection of two/three features, or other methods. For example, consider studies [28,30], which calculated the average, variance, maximum, and entropy of the click time feature at various time intervals, as well as other raw features. Another study [39] separated the click time feature into several time features, such as day, month, and period of day. Section 3 will provide further details on the new features derived using feature engineering.

Table 2. Features in the publisher dataset.

| Attribute | Description | | |
|--|--|--|--|
| publisherid | Unique identifier of a publisher. | | |
| bankaccount | Bank account associated with a publisher (anonymized; may be missing/unknown). | | |
| address Mailing address of a publisher (anonymized; may be missing/unk | | | |
| status | Label of a publisher, which falls into three categories: OK: Publishers whom BuzzCity deems as having healthy traffic (or those who slipped their detection mechanisms). Observation: Publishers who may have just started their traffic or their traffic statistics deviates from system wide average. BuzzCity does not have any conclusive stand with these publishers yet. Fraud: Publishers who are deemed as fraudulent with clear proof. BuzzCity suspends their accounts and their earnings will not be paid. | | |

Table 3. Features in the click dataset.

| Attribute | Description | | | | |
|-------------|---|--|--|--|--|
| id | Unique identifier of a particular click. | | | | |
| numericip | Public IP address of a clicker/visitor. | | | | |
| deviceua | Phone model/agent used by a clicker/visitor. | | | | |
| publisherid | Unique identifier of a publisher. | | | | |
| campaignid | Unique identifier of a given advertisement campaign. | | | | |
| usercountry | Country from which the clicker/visitor is. | | | | |
| clicktime | Timestamp of a given click (in yyyy-mm-dd format). | | | | |
| referredurl | URL where ad banners are clicked (anonymized; may be missing/unknown). Publisher's channel type, which consists of: | | | | |
| channel | ad: Adult sites. co: Community. es: Entertainment and lifestyle. gd: Glamour and dating. in: Information mc: Mobile content. pp: Premium portal. se: Search, portal, services. | | | | |

4.2. TalkingData AdTracking Dataset

4.2.1. Dataset Description

The TalkingData AdTracking dataset was put up on Kaggle in 2017 as a competition by the Chinese company TalkingData, which processes three billion clicks every day, 90% of which are possibly illegitimate. [80]. Its method of detecting and preventing click fraud is to monitor and analyze users' click journeys across their portfolios; IP addresses that generate many clicks but never install apps are flagged. A blacklist of IP addresses and devices is then created based on this information. The goal of the competition was to develop the best model for predicting whether a user would proceed to install an app after clicking on an ad and to distinguish fraudulent clicks from benign ones. The data provided were extensive, comprising a total of 203,694,359 real-time ad click records captured on a mobile platform, with an overall size of roughly 7 GB over four days. Table 4 illustrates the statistics of the TalkingData dataset.

| | | | No. of Publishers | |
|---------------|--------------------------|---------------------------|-------------------------|-----------------------------|
| Dataset | Time Period | No. of Clicks | Fraudulent | Non-Fraudulent |
| Train Test | 6 Nov 2017 9 Nov 2017 | 184,903,890 18,790,469 | 509,235.8975 (0.25%) | 203,185,123.103 (99.75%) |

Table 4. Statistics of the TalkingData dataset.

4.2.2. Raw Features

The TalkingData dataset is generated from mobile phones and is widely used by studies in recent years to build and train click fraud detection models and approaches. It has millions of clicks distributed among eight features. These features are described in detail in Table 5; seven of these features are considered independent features, whereas one is deemed dependent (Is_attributed feature. It is the class that will be predicted; a value of 0 indicates a legitimate/non-fraudulent click, whereas a value of 1 indicates a fraudulent click). Some studies used raw features as they are, whereas others added primitive feature engineering. For instance, several studies have focused on extracting temporal features, such as minutes and seconds, from the click time feature [42,47,48,53,58,75] and on grouping IP features along other attributes in a combination of one/two attributes [42,48,69]. Section 3 provides the details of the new features derived using feature engineering.

Table 5. Features in the TalkingData dataset.

| Attribute | Description |
|-----------------|--|
| ip | Ip address of click. |
| app | App id for marketing. |
| device | Device type id of user mobile phone. |
| os | OS version id of user mobile phone. |
| channel | Channel id of mobile ad publisher. |
| click_time | Ad timestamp of click (UTC). |
| attributed_time | If user download the app after clicking an ad, this is the time of the app download. |
| is_attributed | the target that is to be predicted, indicating the app was downloaded. |

4.3. Avazu Click-Through Rate Prediction Dataset

4.3.1. Dataset Description

The Avazu dataset was also presented on the Kaggle platform in 2014 [81]. As part of a competition hosted jointly by Avazu and Kaggle to determine the best strategy for predicting the CTR, which is a vital measure for analyzing ad performance. The dataset includes around 40 million records captured over 11 days, with 10 days serving as the training set and 1 day serving as the test set. Click prediction systems are critical, and they commonly use sponsored searches to rank ad links. The goal of CTR prediction is to estimate the likelihood that advertisements on a website will be clicked. By predicting the CTR, an advertising agency selects the potential visitors who are most likely to engage with the advertisements. Table 6 illustrates the statistics of the dataset.

Table 6. Statistics of the Avazu click-through rate prediction dataset.

| | | Class of Clicks | | |
|---------------|-------------------------|--------------------|-----------------|--|
| Dataset | No. of Clicks | Non-Clicked | Clicked | |
| Train Test | 40,000,000 4,600,000 | 40,140,000 (0.25%) | 4,460,000 (10%) | |

4.3.2. Raw Features

The dataset includes 21 distinct features, some of which describe the ad, such as the ad ID and position, as well as features describing the source of the click, such as device

type and connection type. The target feature is the click class, which is binary: 0 means that an ad was not clicked, and 1 indicates that the visitor clicked an ad. About eight out of the 21 features in the dataset are anonymous, as illustrated in Table 7. These are categorical fields that contain specific data about users' and advertisers' profiles and are hashed to a unique value to enable investigators to construct vectors [82]. These anonymous fields and their meanings were not publicly revealed or investigated in the studies we examined in the literature review; however, there were some efforts in other experiments in which it was inferred that C14 is the ad ID, C17 is the ad group ID, and C21 is the ad sponsor ID on the basis of interpreting the hierarchy of unknown features [83]. All the studies that applied this dataset in the literature review used all the information provided in the dataset to detect click fraud, along with separating the click time feature into month, day, and hour and determining the frequency of clicks in 10 h [47,74,75].

Table 7. Features in the Avazu click-through rate prediction dataset.

| Attribute | Definition |
|------------------|---|
| ID | The unique identifier for all details that corresponds to one occurrence of an advertisement. This is a continuous variable. |
| Hour | The hour, in YYMMDDHH format. We could break this down and add additional features during the cleaning process. This is a continuous variable. |
| Banner_pos | The position in the screen where the advertisement was displayed. This shows the prominent place for an advertisement to get the attention of the user. This is a categorial integer |
| Site_id | The identifier to unique identify a site in which the advertisement was displayed. This is a hashed value. |
| Site_domain | The domain information of the website in which the advertisement was displayed. |
| Site_category | This is a categorical variable representing the field to which the website belongs to. This can be used 27 to understand if any site category has more visitor attraction during any particular time. |
| App_id | The identifier to unique identify a mobile application in which the advertisement was displayed. This is a hashed value. |
| App_domain | The domain information of the application in which the advertisement was displayed. |
| App_category | This is a categorical variable representing the field to which the application belongs to. This can be used to understand if any app category has more visitor attraction during any particular time. This is similar to the site category and can be compared relatively to check if app has more clicks over the website. |
| Device_id | The unique identifier that marks the device from which the click was captured. This is a hashed continuous variable and can be repeated in the data set. |
| Device_ip | The ipv4 address of the device from which the click was received. Hashed to a different value for privacy reasons to avoid trace back to the device. |
| Device_model | The model of the device. We choose not to use this value. |
| Device_type | The type of the device, is a categorical variable and has around 7 categories. |
| Device_conn_type | This is a hashed value about the connection type. We do not use this value for forming the vector. |
| C1 | An anonymous variable. It has influence over the prediction. |
| C14–C21 | Anonymous categorical variables that might have information about the advertisers' profile and the users' profile like the age, gender, etc. |
| Click | The target variable, 0 means an advertisement was not clicked and 1 means the ad was clicked. This is a categorical variable, binary typed. |

4.4. Challenges in the Common Datasets in the Field of Click Fraud Detection

Most datasets related to click fraud detection suffer from imbalance, with the majority of the negative class (i.e., fraudulent clicks) being few and the benign class (i.e., legitimate clicks) compensating for most data records, causing the prediction model to be skewed toward the majority. Previous studies used various resampling procedures, such as up/down sampling and the SMOTE. In up-sampling, minority samples are reproduced until they are equal to those from the majority class. Under-sampling, on the other hand, excludes from the majority class at random until the class distribution is balanced. This issue was addressed in the FDMA 2012 BuzzCity datasets by implementing several workarounds. Under-sampling, for example, was used to overcome the problem of dataset imbalance in study [33], in which certain majority-class records were chosen for use along with all minority-class records. In another study [42] to address the same issue, the process was

carefully aimed at minimizing information loss caused by undersampling or overfitting because of oversampling. As a result, the following approach was used: oversampling positive samples and undersampling negative samples. Furthermore, the QDPSKNN method [62] was applied to address dataset imbalance, along with reducing capacity needs and improving implementation performance. It divides the data into four quadrants and then undersamples to balance class distribution. The authors in [34] also illustrated that to deal with imbalanced class distribution, in nonlinear classifications involving combinations of variable types and noisy or missing patterns, tree-based ensemble classifiers and backward feature exclusion can produce promising results.

On the other hand, the TalkingData dataset also suffers from a massive imbalance, with legitimate clicks representing only 0.25% ((Is_attributed feature = 0) of all clicks in the entire dataset, while fraudulent clicks ((Is_attributed feature = 1) represent 99.75%. The problem with the model being trained on an imbalanced dataset is that it will be skewed exclusively toward the majority class. This presents an issue when we are concerned with the prediction of the minority class. Several efforts have been made in earlier studies to overcome this challenge when training models. For example, a 15% random selection of unique IPs was used, followed by an 8% stratified sample from the rest to decrease the data size in [61]. To address the imbalance, the SMOTE [84] with neighbors = 5 was used, and the positive class oversampled by 11%. In [59], however, undersampling was used to balance skewed datasets by preserving all data in the minority class and decreasing the volume of the majority class. The authors suggested that the test set should be more comprehensive, so the original training set was divided into two new training and test sets, and then additional samples were drawn from the new test set by selecting the is_attributed feature = zero and one click in a 1:1 ratio, resulting in a dataset that contains 50% legitimate and 50% fraudulent clicks. Furthermore, they trained all the different ML models using variable samples of training data; the goal of changing the training sample sizes was to enhance precision while lowering overfitting. In another effective way to address this issue [66], the entire dataset was divided into six classes based on the IP and app ID features as follows: class 1: 25,974 rows with a unique IP count < 20 and an app ID frequency < 70%; class 2: 27,174 rows with a unique IP count in the range => 20 and < 1000and app ID frequency < 70%; class 3: 112,790 rows with a unique IP count => 1000 and an app ID frequency < 70%; class 4: 784,964 rows with a unique IP count < 20 and an app ID frequency = 70%; class 5: 19,914,810 rows with a unique IP count in the range = 20 and <1000 times and an app ID frequency =>70%; and class 6: 164,038,178 rows with a unique IP count => 1000 and an app ID frequency => 70%. The classifiers were tested separately on each of these classes. In another study [56], the model was trained using only the first class.

And according to the statistics in Table 7, there is a significant disparity in the Avazu click-through rate prediction dataset, with the percentage of those who viewed the ad but did not click on it being 90%, and the percentage of those who viewed the ad but clicked on it being 10%. All the studies in our literature review used one million samples from the dataset [74,75], and applied undersampling technique to balance the dataset [50].

5. Common Features in Click Fraud Detection Using AI Techniques

In this section, we review the most frequently used features in AI-based click fraud detection techniques. We explain which features were considered in previous studies and their meanings, as well as which features were deemed essential for detecting ad click fraud.

A click request is transmitted to the Ad Manager ad server whenever a user clicks on any ad. When the ad server receives the request, it counts the clicks and directs the user to the landing page. As we all know, these clicks can come from real people who are interested in advertising or from a bot. Furthermore, advertising campaigns are managed either by the provider (e.g., Google Ads) or by a third party (e.g., marketing and advertising agencies), and one of the tasks in managing advertising campaigns is to prevent and block bot clicks as much as possible using various effective techniques, such as filtering or restricting click activity. For instance, a bot is identified as an IP/host that has made clicks greater than the THRESHOLD TOTAL clicks during that same day or greater than the THRESHOLD HOURLY clicks at any hour of a given day. The thresholds THRESHOLD TOTAL and THRESHOLD HOURLY can be changed [85]. To effectively manage advertising campaigns, the provider or third party stores a variety of click-related features, which can be used to monitor and respond to advertising performance, calculate advertiser costs, prevent unauthorized clicks, or make other decisions. Some features can be captured from the browser and JavaScript. This is because JavaScript is implemented by at least 98% of web browsers [86], and most online advertising platforms rely on JavaScript functionality, such as recording mouse movements, keystroke events, or IP addresses, in addition to several temporal-spatial features [70].

5.1. Descriptions of the Most Commonly Used Features in Ad Click Fraud Detection

As illustrated in Table A1, prior ad click fraud detection efforts have mainly focused on accurate and careful data pre-processing and feature generation, as these are crucial phases that considerably enhance the overall accuracy of click fraud detection models. Malware, bots, and competitors frequently simulate their malicious activities by using a variety of methods, such as producing very sparse click sequences, changing IP addresses, and generating clicks from multiple machines in various locations. As a result, studies have been carried out to investigate click sources and user behavior during and after clicking on an ad. Most of these works have examined temporal characteristics; for example, in [29], an essential factor, click profile, or the time delay between consecutive clicks, was explored. Two types of click profiles were recorded—long and short. Both types calculated the number of clicks generated from the same IP address per day, which was measured at less than 5 s, between 5 s and 10 s, between 10 s and 20 s, between 20 s and 30 s, and so on over an interval >300 s. The difference of the two types is that the long profile should be at least 10 clicks from the same IP, whereas the short profile should not be fewer than five clicks from the same IP.

Furthermore, click timestamp was split into smaller segments, such as month, day, hour, minute, and second [31,36,42,45–47,56,58,69,74,75], to investigate click behavior in the smallest possible detail. Bot clicks frequently have patterns after an ad is clicked because their behavior when interacting with the landing page is minimal or almost non-existent, as demonstrated in [36]; for a click to be considered legitimate, one of the following criteria must be met: 30 s of dwell time, 15 mouse events, and 1 click; or 30 s of dwell time, 10 mouse events, 1 scroll event, and 1 click; and so on. Other experiments, such as [27,28,31,32,35,38,40,43,46,60,62,66,73], have attempted to construct more precise features with regard to click time and other features, such as the total number of clicks or devices used, by identifying each attribute individually and then modeling the click pattern according to that attribute through the generation of several parameters depending on the attribute. These parameters are determined using statistical measurements, such as maximum, mean, skew, and variance; for example, some features are Var5mins, Var10mins, Var1hr, Var2hrs, Var6hrs, or AvgClicksPer5Min, MaxClicksPer5Min, Varper5minclick, and MaxClicksperMin.

According to recent data [87], throughout the weekdays of an advertisement campaign in 2022, there was a major increase in bots' activities, with bots peaking around noon (Pacific Daylight Time) and uniformly growing from 0 to 800 per hour before returning back to 0 per hour after the noon peak during the week. On weekends, bot numbers decrease practically to none. The period of day may indicate a higher likelihood of illegitimate clicks. In another set of recent statistics [88], the most active period of day for bots was 1–2 pm worldwide in Eastern Standard Time, and the least active period was 9–10 pm. As a result, several studies [27,32,36,40,43,56,62] have focused on these two critical aspects when detecting click fraud. They split a day into numerous segments, such as morning, afternoon, and midnight. They also indicate whether it is weekday or weekend. There are few published studies that have considered user behavior [33,50,56,67]; for example, in some experiments, features such as the number of scrolling events, the number of mouse movements, keystroke data, and the types of actions that a visitor made after clicking are used to detect click fraud. Some studies have relied on IP reputation as well, reasoning that any malicious action from an IP address indicates that all activities from that IP address are likely to be illegitimate. As a result, IP blacklists were constructed, and bots running from blacklisted IP addresses were prevented. In other research, features were introduced as groups of two or three rather than individually [48,69].

Table A2 in the Appendix B shows a list of all the features used in previous studies ("used features" in Table A1), which are classified as follows: temporal, spatial, user behavior, used medium, IP address, number of clicks, provider or advertiser, and other features.

To ensure that there was no dispersion, we standardized the names of features across all studies that were included in our literature review. In spite of this, we ensured that the names were precisely standardized, and that the features' names were re-emphasized to reflect their meanings and accurate descriptions.

5.2. Discussion of the Features Used

In this sub-section, we explore and illustrate the most essential features that were considered significant when training models and building systems that can detect click fraud at a high level of certainty. As seen in Tables 1 and 7, most studies did not use features in their raw form but rather processed and engineered them in various ways to improve the accuracy of malicious click detection while avoiding the overfitting or underfitting of models. As a result, a properly engineered and selected feature set should be able to capture characteristics or trends relevant to fraudulent clicks and be robust to the changing patterns of behavior used by malicious parties. These malicious parties who launch fraudulent clicks may follow standard procedures by launching a series of chain clicks at periodic intervals. Alternatively, the process may be changeable and may mask its activities using various techniques, such as generating many clicks in a very spread and random way or generating clicks from different devices or countries. It is critical that the model detect and capture both forms of click fraud attacks.

It is worth noting that ad websites infected with click fraud rank significantly differently on the websites rank checker such as [89], with fraudulent parties targeting both large and small domains. Even well-known and reputable domains may be attacked [28]. Websites offering mobile-related content or adult content, for example, receive a high volume of illegitimate clicks, particularly late at night or early in the morning. Next are sites with entertainment and lifestyle content, which tend to have an increase in illegitimate clicks in the afternoons and evenings [35]. Definitely, other features have been obtained and engineered, but we now discuss the key aspects of the features used to identify illegitimate clicks.

5.2.1. Temporal Features

To analyze click patterns and behaviors, previous studies have investigated and evaluated temporal features to capture both short- and long-term click behaviors. This is because malicious parties frequently attempt to act logically and make consistent clicks across highly varying periods of time. Furthermore, several statistical approaches, such as calculating variance, skewness, and standard deviation, have been applied to the temporal features of the number of clicks at specific intervals of time. For instance, calculating the click variance at each time interval provides knowledge of a party's click pattern, whereas click skewness determines the divergence of the number of clicks from a party's average clicks at a given period [31]. Moreover, temporal features are constructed in a variety of ways, including breaking down the timestamp into further information, such as the month, day, minute, and second when the click occurred. Day has also been divided into different time intervals in several studies; for example, a day is divided into four 6 h categories: night (12 a.m.–5:59 a.m.), morning (6 a.m.–11:59 a.m.), afternoon (12 p.m.–5:59 p.m.), and evening (12 p.m.–5:59 p.m.) (6 p.m.–11:59 p.m.). Splitting a day into numerous parts helps determine the temporal patterns of clicks [30,32]. In addition, 1 h is also divided into four 15 min periods: first (0–14), second (15–29), third (30–44), and last (45–59). The third 15 min

period, for example, is the number of clicks between the 30th and 44th minute divided by the total number of clicks [34].

5.2.2. Spatial Features

The location of the clicker is associated with click fraud [29], particularly manual click fraud [42]. As a result, the geographic features of the click source, such as country, city, or area from which the click originated, are considered. Countries that generate a large number of clicks are investigated and evaluated as groupings or clusters, whereas clicks from exceptionally small countries are studied and analyzed individually. For example, distinct countries were analyzed, including the percentage of clicks generated by each city, in [35], and the number of clicks from the same country and the variance and skewness of these clicks were examined in [31]. The proportion of clicks from each country across various periods was also studied in [32].

5.2.3. Clicker Behavior Features

Before, websites simply banned all bots because of clear and poor bot-like behavior patterns, but as technology evolved, bot behavior became more complicated, demanding in-depth research and monitoring. Otherwise, organizations risk banning valid customers and good bots, and, worst, they risk bots taking over customer accounts and destroying the brand name. There are several indicators of bot behavior that every organization should be aware of. Speed is a useful indicator because robots are designed to outpace humans. It can also be a feature of bot behavior, in addition to unusual IP addresses or traffic from unfamiliar countries. Nevertheless, the complexity of bot behavior is developing and evolving on a daily basis, so it is essential to evaluate a typical user journey and consider what an unusual journey may look like [90].

As many bots attempt to mimic human behavior on advertisers' post-click sites, there has been little attention to the study of post-click behavior. Few studies have examined human-like behavior to determine whether the origin of clicks is real or a bot [33,50,56,67]. Mouse movements, keystroke data, surfing duration, number of pages viewed after clicking, and fields filled out are among the behavioral characteristics that have been investigated. It is vital to highlight the distinct differences between the activities and behaviors of a real human and a bot on an advertiser's site following the ad click. For example, in [36], a threshold was set for a number of events to distinguish between legitimate and illegitimate clicks. To be classified as legitimate, an ad click must satisfy at least one of the following criteria: (1) 30 s for surfing, 15 mouse events, and one click; (2) 30 s for surfing, 10 mouse events, one scroll event, and one click; and (3) 30 s for surfing, 10 mouse events, and two page visits. According to a recent study [91], bots are categorized into eight groups based on their behavior after the ad click. One example is sit-in bots, which are the most common. They leave a page after clicking and going to the landing page and after spending a certain amount of time on it; they do not do any actions on the advertiser's site. Another is long-distance lovers bots, which use VPNs or other impersonation techniques to appear to be users from particular locations. The third is scrapers, which produce 5000 clicks for each advertiser's site. These bots are designed to gather data and content from the site and spread it to other websites.

5.2.4. Medium and IP Features

To make things more complicated, bots are increasingly using the same technology as real humans. They use browsers with fingerprints; that are highly similar to human browsers and can, for example, leverage mobile phone farms to exploit real hardware rather than simulated hardware [92].

Several aspects of the medium, including the equipment or device used to produce the click, have been investigated to address this issue. This comprises a variety of factors, such as platform type (e.g., mobile phone or laptop), browser, OS, agent, and ISP. According to recent statistics, the Mozilla Firefox and Microsoft Edge browsers had the lowest percentage

of visits to bots' fraudulent advertisements in 2022, with 13.5% and 17.9%, respectively. Yandex and Opera, on the other hand, had the highest rates of ad fraud, with 29.4% and 26.3%, respectively. The Windows OS generated the most bot and ad fraud traffic. Desktops had the highest rate of bots and ad fraud in the second quarter of 2022, which was at 22.2%. Mobile ad bot traffic was 13.3%, approximately nine percentage points lower than desktop ad bot traffic [93]. Therefore, medium-related characteristics were analyzed using data obtained by JavaScript, such as browser type, language used, OS, and screen resolution, or data were collected in alternative ways for the purpose of identifying and examining malicious party patterns and preventing false clicks. Furthermore, IP-related features were obtained and engineered because the same IP can produce many sequential clicks or clicks at specific intervals. Bots may traverse millions of clean residential IP addresses. Usually, each IP address makes only one or two click requests before the bot switches on to another [94]. Some calculations, such as the variance of the IP clicks factor, were also done to assess IP patterns properly because it is suspicious that a single user, perhaps a click bot, performs a constant number of clicks from many IP addresses. Similarly, a clicker with a bad IP address, such as a scam or one on the IP blacklist, is extremely likely to create false clicks [36].

5.2.5. Ad-Related Features

Some studies have considered features associated with the clicked ad, such as information about the ad publisher, advertiser, ad campaign [26,28,30–32,41,48,65,73], as well as information about ad placement on the website, such as ad size on the screen and the distance between the ad and other elements of the web page [35,50,65]. Furthermore, it has been pointed out that investigating publishers' reputation is critical because some clicks originate from shady websites. Although historical features (e.g., the number of previous clicks at different periods, click rate of a specific city, and web pages in history) have been shown to have a higher descriptive power for click behavior than the contextual features of an advertisement (e.g., the location of the ad on screen and the number of ads in one web page) [37], this does not negate the ability of contextual features to clearly describe malicious fraud patterns and support the performance of click fraud detection models [38]. Furthermore, contextual features are critical in dealing with the issue of cold start. Contextual aspects are essential for predicting click identity for new users and advertisements.

5.3. Insights Derived

The primary findings of previous studies demonstrate that after several experiments with different models used to classify ad clicks as legitimate or illegitimate, some features offered more evident hints and clues to identify ad click fraud than others did, and these were considered vital indicators of fraud detection. These insights are explained in the following.

Notably, most previous studies did not identify the most significant critical features after experiments were conducted. Some did not even include FS approaches for identifying feature importance and choosing the best possible feature subset, or perhaps they did not declare this explicitly in their studies.

- Fraud detection relies heavily on features gathered from fine-grained time-series analysis [26,30,31,37,38,40,54,69,73]. The use of basic statistical calculations of temporal characteristics may preserve strong predictive ability across time while reducing the likelihood of overfitting the training data. The interval of the day (e.g., night and morning) is the most influential factor in [39], followed by the type of day. Time of day appears to be the least influential attribute;
- An adequate analysis of the spatio-temporal aspects of click traffic is required for effective fraud detection [29,30];
- Fraudulent clicks are more frequent in some countries (or finer-grained geographical locations) than in others. Geographical features, such as clicks from high-risk countries, might be used as fraud indicators [34];

- Clicks from the same device or IP address that are duplicated may be invalid clicks [48,69]. Similarly, a clicker with a bad IP address, which is on the IP blacklist, is extremely likely to create false clicks [36];
- The clicker's behavior on the advertised site (i.e., the user's browsing behavior data) is a critical aspect in verifying the clicker's identity [33,38,50]. Unfortunately, only a few previous studies have focused on investigating and monitoring clicker behavior on an advertiser's site; it is undoubtedly a significant signal that distinguishes fraudulent clicks from genuine ones;
- Another useful method for identifying fraudulent clicks is to observe mouse events. When visiting a website on a nonmobile platform, a human user must perform a mouse action at least once. The lack of mouse action identifies this click as invalid. However, this may not be the case for mobile platform users. Therefore, some methods were developed exclusively to test mouse event behavior on nonmobile platforms [36];
- One basic method for detecting fraudulent clicks is to check whether the computer supports JavaScript [36];
- It is necessary to track the number of ad clicks every day, as well as the frequency of each click, in order to make a reliable conclusion [60]. Duplicated clicks are most likely illegitimate clicks [34];
- Clicks that come from suspicious sites are highly likely to be fraudulent clicks [36];
- Historical features explain aggregated user behavior over time, and they are far more reliable than contextual features; however, contextual aspects are essential for predicting click identity for new users and advertisements [37];
- Ad placement control features, such as the acceptable number of ads on the screen, the visibility of the ad on the screen so that it is not hidden behind another element, the size of the ad displayed on the screen, and the distance between the ad and other clickable elements, such as buttons, are key aspects of click fraud detection [38].

6. Discussion

In this section, some of the points raised in the review of previous studies are presented, which can serve as recommendations or insights for ongoing and evolving attempts to detect click fraud effectively and robustly in future models or systems.

- There is a limited number of publicly available datasets, which may restrict the potential for wider and more in-depth investigations of PPC and click fraud. As a result, there is a need for fresh and diverse public datasets;
- All public datasets suffer heavily from negative class imbalance, which causes models to overclassify the greater class(es) because of the increased likelihood of their appearance; as a result, the model is biased toward the majority group. Dealing with this imbalance would require extensive processing;
- Clickers' behavior after visiting an advertiser's website has not been sufficiently explored, which is certainly an important factor in distinguishing human clicks from bot clicks. Most studies have not investigated behavioral aspects, as these are either not accessible in the (mainly public) datasets or are neglected and not of interest;
- Checking the legality of an IP address and whether it is on an IP blacklist may be valuable, but given the intelligence and sophistication of bots, it should not be heavily relied on, especially that bot creators use residential IP addresses to mask their bots as normal traffic. Bots can also spoof the IP addresses of other legitimate users;
- Integrating features as a combination of two or three features may be a promising step toward the more effective detection of click fraud and must be used with caution because it has been used in very few studies;
- According to Lyu et al. [95], current feature interaction models and techniques are broadly categorized as follows: (1) naive methods, which do not model feature interactions and use only raw features; (2) memorized methods, which explicitly present feature interactions as novel features and allocate trainable embeddings for them; and (3) factorized methods, in which raw features are transformed into latent vectors and

feature interactions are implicitly modeled across factorization functions. Most prior efforts to detect ad click fraud used the first two types of approaches; thus, including the third type and modeling feature interactions using factorization functions may yield excellent outcomes for click classification;

- Using numerous DL models may lead to superior classification and prediction performance and effectiveness. These can also be used to directly extract features, such as deep NNs, and an efficient feature set;
- Finally, detecting click fraud is a never-ending cat-and-mouse game, as bot creators are always seeking new methods to defeat bot detection systems. The process of building systems to identify and prevent click fraud should continue because bots are constantly evolving over time. Advanced solutions to prevent and deal with them are required.

7. Conclusions

Modern marketplaces are threatened by the widespread occurrence of click fraud. This happens when people click on ads to generate revenue for the application's publisher, not out of interest in the ads. Click fraud drains advertising expenses and threatens the future of the online advertising marketplace by diverting cash from legal partners (publishers). It exploits the PPC billing scheme to create illegitimate ad click requests; in 2021, click fraud accounted for \$42 billion in advertisers' losses [96,97]. Several successful attempts have been undertaken to detect and prevent this type of fraud. Among the most popular approaches is AI, namely, ML and DL, which have been extensively explored in this study. The focus has been on examining the features used previously for click identification (benign or fraudulent) and then determining the most critical ones that are considered strong evidence of click fraud. Nonetheless, as bots and technology evolve, click fraud detection and prevention systems must also evolve to keep up with the complexity of bots and deal with this problem rapidly and effectively.

|------|--|--|--|--|
| [60] | LR and GNB. | Public Kaggle AdTrackin TalkingData Dataset. | IP, Agent, Channel Id, App Id, Attributedtime, OS, Click time, Is attribute, #Clicks daily, and Click frequency. | GNB.Accuracy = 99.76%, GNB.Recall = 99%, and GNB. <i>F</i> 1-Score = 100%. |
| [61] | Catboost. | Private Dataset "mobile.de": Train-set: 200,000 records. Test-set: 240,000 records. And a part of the public Kaggle AdTrackin TalkingData Dataset. | 1st dataset: (Confidential 27 features). 2nd dataset: IP, App Id, Agent, OS, Channel Id, click time, Day, and hour. | On 1st dataset: F1-Score = 71.27%, Precision = 73.35%, Recall = 68.95%, and AUC = 98.09%. On 2nd dataset: F1-Score = 98.88%, Precision = 99.02%, Recall = 98.73%, and AUC = 99.94%. |
| [62] | QDPSKNN. | FDMA2012 BuzzCity Dataset (click dataset only) | Same as Ref. [35] | 1st dataset: Precision = 75.1%, Recall = 70.1%, <i>F</i> 1-Score = 72.5%, and G-mean = 73.3%. |
| [52] | Deep Convolutional Neural Network (DCNN), SVM, RF, DT, AdaBoost, and GBT. | FDMA2012 BuzzCity Dataset. | Same as Ref. [35] | GTB.Precision = 79.8%, GTB.Recall = 70.8%, GTB.F1-score = 72.4%, and GTB.AUC = 92.4%. |

Appendix B

Table A2. A brief description of all features used in previous studies (included in the literature review).

| Features | Descriptions |
|---|---|
| | Temporal Features |
| Click time | Timestamp of ad click in Coordinated Universal Time |
| Hour | Hour of day when the click was made |
| Minute | Minute of hour when the click was made |
| Second | Second of minute when the click was made |
| Period | Period of day when the click was made: midnight, early morning, morning, midday, evening, and night |
| #Clicks in periods | Total number of clicks in the evening (18:00–24:00) and at night (00:00–06:00) |
| % Clicks in periods | Percentage of clicks belonging to each publisher in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| %Referredin periods | Percentage of distinct referred URLs belonging to each publisher in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| %Agentin periods | Percentage of distinct agents belonging to each publisher in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| Month | Month of the year when the click was made |
| Day | Day of the week when the click was made |
| Day type | Weekday or weekend |
| Date | Date of the day when the click was made |
| Long click profile | #Clicks per day generated from the same IP address were measured in intervals lower than 5 s, from 5 s to 10 s, from 10 s to 20 s, from 20 s to 30 s, and so on up to 300 s; must be at least 10 clicks in the same IP |
| Short click profile | #Clicks per day generated from the same IP address were measured in intervals lower than 5 s, from 5 s to 10 s, from 10 s to 20 s, from 20 s to 30 s, and so on up to 300 s; must be at least five clicks in the same IP |
| URL profile | #Clicks per day generated from the same IP address were measured in intervals lower than 5 s, from 5 s to 10 s, from 10 s to 20 s, from 20 s to 30 s, and so on up to 300 s; must be at least five clicks in the same IP |
| Avg #Clicks per 1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h | Average number of clicks for each partner during time intervals of 1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h |
| Max #Clicks per 1 min, 5 min, 1 h, 3 h, and 6 h | Max number of clicks for each partner during time intervals of 1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h |
| Var #Clicks per time intervals (1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h) | Variance number of clicks for each partner during time intervals of 1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h |
| Skew #Clicks per 1 min, 5 min, 1 h, 3 h, and 6 h | Skewness number of clicks for each partner during time intervals of 1 min, 5 min, 10 min, 1 h, 2 h, 3 h, and 6 h |
| #Clicks per 1 min | Number of clicks for each partner per 1 min |
| #Visitors per 1 min | Number of visitors for each partner per 1 min |
| #Ads per 1 min | Number of ads for each partner per 1 min |

| #Agent per 1 min Number of agents for each partner per 1 min #Ctry per 1 min Number of referrer URLs for each partner per 1 min #Referrer per 1 min Number of referrer URLs for each partner per 1 min #Clicks adrend per 1 min Percentage of the number of clicks from the same device IP per 1 min #Clicks adrend per 1 min Percentage of clicks from the dab nance per 1 min #Clicks adrend per 1 min Percentage of clicks from the device agent per 1 min #Clicks adrend per 1 min Percentage of clicks from the referrer URL per 1 min #Clicks referrer ratio per 1 min Percentage of clicks from the referrer URL per 1 min #Clicks referrer ratio per 1 min Percentage of clicks from the referrer URL per 1 min #Areage, STD, count IP in s Average, standard deviation, and total IP visits per second Avg, STD, count IP in n Average, standard deviation, and total IP visits per nour Count IP En hour Total number of visits (>2) by IP + agent per day Count IP in hour Total number of visits (>2) by IP + agent per day Count sub-IP in min Total number of visits (>2) by subnetwork (divided by 1,000,000) per second Count sub-IP in min Total number of visits (>2) by subnetwork (divided by 1,000,000) per ady Count sub-IP in min To | Features | Descriptions |

| agent, creative, project, and position in hMean (variance) of clicks, cookie, agent, creative, project, and position in hoursMean (var) clicks, cookie, agent, creative, project, and position in minMean (variance) of clicks, cookie, agent, creative, project, and position in minutesMean (var) clicks, cookie, agent, creative, project, and position in sMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) clicks, cookie, agent, creative, project, and position in sMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) of intervalsMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) of intervalsMean (variance) of clicks, cookie, agent, creative, project, and position in secondsAttributed timeTime of the first action performed by the user after clicking (e.g., download app)First 15 min percentNumber of clicks from the 1st to the 14th minute divided by the number of clicksSecond 15 min percentNumber of clicks from the 15th to the 29th minute divided by the number of clicks | #Clicks same IP in s | |
| agent, creative, project, and position in minMean (variance) of clicks, cookie, agent, creative, project, and position in minutesMean (var) clicks, cookie, agent, creative, project, and position in sMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) of intervalsMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) of intervalsMean (variance) of click intervalsAttributed timeTime of the first action performed by the user after clicking (e.g., download app)First 15 min percentNumber of clicks from the 1st to the 14th minute divided by the number of clicksSecond 15 min percentNumber of clicks from the 15th to the 29th minute divided by the number of clicks | agent, creative, project, and | Mean (variance) of clicks, cookie, agent, creative, project, and position in hours |
| agent, creative, project, and position in sMean (variance) of clicks, cookie, agent, creative, project, and position in secondsMean (var) of intervalsMean (variance) of click intervalsAttributed timeTime of the first action performed by the user after clicking (e.g., download app)First 15 min percentNumber of clicks from the 1st to the 14th minute divided by the number of clicksSecond 15 min percentNumber of clicks from the 15th to the 29th minute divided by the number of clicks | agent, creative, project, and | Mean (variance) of clicks, cookie, agent, creative, project, and position in minutes |
| Attributed timeTime of the first action performed by the user after clicking (e.g., download app)First 15 min percentNumber of clicks from the 1st to the 14th minute divided by the number of clicksSecond 15 min percentNumber of clicks from the 15th to the 29th minute divided by the number of clicks | agent, creative, project, and | Mean (variance) of clicks, cookie, agent, creative, project, and position in seconds |
| First 15 min percentNumber of clicks from the 1st to the 14th minute divided by the number of clicksSecond 15 min percentNumber of clicks from the 15th to the 29th minute divided by the number of clicks | Mean (var) of intervals | Mean (variance) of click intervals |
| Second 15 min percent Number of clicks from the 15th to the 29th minute divided by the number of clicks | Attributed time | Time of the first action performed by the user after clicking (e.g., download app) |
| | First 15 min percent | Number of clicks from the 1st to the 14th minute divided by the number of clicks |
| Third 15 min percentNumber of clicks from the 30th to the 44th minute divided by the number of clicks | Second 15 min percent | Number of clicks from the 15th to the 29th minute divided by the number of clicks |
| | Third 15 min percent | Number of clicks from the 30th to the 44th minute divided by the number of clicks |

| Features | Descriptions |
|--|---|
| Last 15 min percent | Number of clicks from the 45th to the 59th minute divided by the number of clicks |
| Avg and STD spiky ReAgCnIpCi | Average and standard deviation of the number of the same referred URL, agent, country, IP, and Cid being duplicated in 1 min |
| Avg and STD spiky ReAgCnIpCi in morning, afternoon, and night | Average and standard deviation of the number of the same referred URL, agent, country, IP, and Cid being duplicated in 1 min in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| Avg and STD spiky referred URL | Average and standard deviation of the number of times the same referred URL is duplicated in 1 min |
| Avg and STD spiky Cid | Average and standard deviation of the number of times the same campaign ID is duplicated in 1 min |
| Avg and STD spiky Cid | Average and standard deviation of the number of times the same country is duplicated in 1 min |
| Avg spiky referred URL in morning, afternoon, evening, and night | Average and standard deviation of the number of the same agent being duplicated in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| Avg and STD spiky agent | Average and standard deviation of the number of times the same agent is duplicated in 1 min |
| Avg and STD spiky IP | Average and standard deviation of the number of times the same IP is duplicated in 1 min |
| Click frequency | Click frequency at different time intervals |
| Avg and STD spiky ReAgCnIp | Average and standard deviation of the number of the same referred URL, agent, country, and IP being duplicated in 1 min |
| Avg and std spiky ReAgCn | Average and standard deviation of the number of the same referred URL, agent, and country being duplicated in 1 min |
| Avg and STD spiky Ag in morning, afternoon, evening, and night | Average and standard deviation of the number of times the same agent being duplicated in 1 min in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| Cat number | Total number of clicks for a publisher in each category (which includes ad: adult sites, co: community, es: entertainment and lifestyle, gd: glamour and dating, in: information, mc: mobile content, pp: premium portal, and se: search and portals and services) |
| Avg and STD #Clicks | Average and standard deviation of the total clicks that occurred every minute for a particular publisher |
| Avg and STD null referrer in periods | Average and standard deviation of the clicks with null URL referrer, in the morning (during the hours 06:00:00–12:00:00 of the day), afternoon (during the hours 12:00:00–17:00:00 of the day), evening (during the hours 17:00:01–20:00:00 of the day), and night (during the hours 20:00–24:00:00 and 00:00:00–06:00:00 of the day) |
| Avg and STD#Clicks in 1 h | Average and standard deviation of a publisher's total clicks acquired in 1 h |
| Avg hourly click CvR | Average conversion rate of all clicks in 1 h. |
| #Clicks at T2 | Total number of clicks made in the past by the same publisher across T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days. |
| Avg clicks at night, morning, afternoon, and evening | Average number of clicks during the night (24:00–5:59), morning (6:00–11:59), afternoon (12:00–17:59), and evening. |
| %Clicks at night, morning, afternoon, and evening | Percentage of the number of clicks during the night (24:00–5:59), morning (6:00–11:59), afternoon (12:00–17:59), and evening (18:00–23:59). |
| Mean period click | Mean of the number of clicks in four periods: night (24:00–5:59), morning (6:00–11:59), afternoon (12:00–17:59), and evening (12:00–17:59) (18:00–23:59). |

| Features | Descriptions |
|--|--|
| STD period click | Standard deviation of clicks in four periods: night (24:00–5:59), morning (6:00–11:59), afternoon (12:00–17:59), and evening (12:00–17:59) (18:00–23:59). |
| Var period click | Variance of clicks in four periods: night (24:00–5:59), morning (6:00–11:59), afternoon (12:00–17:59), and evening (12:00–17:59) (18:00–23:59). |
| Most hour click | Maximum number of clicks in 1 h for each publisher. |
| Avg and STD same URL_Ag_Ctry_Cid in 1 min | Average and standard deviation of clicks generated by each publisher in 1 min when the same field (referred URL, agent, Ctry, IP, and Cid) is duplicated. |
| #Period_clicks/#clicks | Total number of clicks produced by each publisher between the hours of (0–14), (15–29), (30–44), and (45–59) divided by the total number of clicks. |
| | Spatial Features |
| Ctry | Countries from which the clicks received by each publisher were made |
| #Ctry | Total number of countries from which every publisher received clicks |
| %Ctry | Percentage of countries from which every publisher received clicks |
| Unique Ctry | Distinct countries. |
| %Clicks certain Ctry | Percentage of clicks coming from different countries (AZ, ID, IN, US, NG, TR, RU, TH, SG, UK, and others) out of the total clicks for a particular publisher |
| Popular area | The most common area where clicks are generated. |
| Ctry/click ratio | Average click ratio for each country. |
| Ctry entropy | Entropy of the click distribution in each country. |
| Max #Clicks same Ctry | Total number of clicks originating from the same country; the maximum of this is then obtained. |
| Var #Clicks same Ctry | Total number of clicks originating from the same country; the variance of this is then obtained. |
| Skew #Clicks same Ctry | Total number of clicks originating from the same country; the skewness of this is then obtained. |
| Click fraction from top 20 ctry | Fraction of the number of clicks from the top 20 countries (top 20 click-producing countries) |
| Click fraction from non-top 20 ctry | Fraction of the number of clicks from the other/non-top 20 countries (least 20 click-producing countries) |
| Click fraction from UN/NA ctry | Fraction of the number of clicks from unknown/empty countries |
| City | Cities from which the clicks received by each publisher were made. |
| Area | City district in which the user resides. |
| Unique Ctry at period T2 | Number of different countries associated with the publisher at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days. |
| Avg and STD of unique Ctry at period T1 | Average and standard deviation of the number of different countries for publishers at T1; T1: per minute, 5 min, 15 min, hour, 3 h, 6 h, and 1 day. |
| Ctry ratio at T2 | Ratio of different countries to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days. |
| STD same Ctry T2 | Standard deviation of the number of clicks for different countries at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days. |
| Max same Ctry T1 | Maximum number of clicks for different countries at T1; T1: per minute, 5 min, 15 min, hour, 3 h, 6 h, and 1 day. |
| Ctry entropy T2 | Number of clicks entropy corresponding to different countries at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days. |

Agent ID

| Features | Descriptions |
|--------------------------------|--|
| #Click from differ Ctry | Number of clicks from different countries. |
| | User Behavior Features |
| Event ID | Unique identifier of the action taken by the user after clicking on the ad, such as watching a video or making a purchase |
| Event timestamp | The time the user's action occurred after clicking on the ad |
| Event count | Number of times the user has undertaken a particular action |
| Max event count | Sum of the number of times the user has undertaken a particular action; its maximum is then obtained. |
| Unique event | Number of times the user has undertaken a previously unknown and unique given action |
| Unique event groups | Number of times the user has undertaken a previously unknown and unique given action within a certain event group (e.g., a group of mouse events and a group of text events) |
| Surfing time | Duration of time the user has spent surfing the advertiser's website in seconds |
| Mouse clicks count | Total number of clicks made on the advertised website |
| Mouse clicks on other pages | Total number of clicks done on pages other than the landing page. |
| Mouse clicks on links | Total number of clicks on hyperlinks |
| #Mouse scroll | Total number of scroll events |
| Mouse scrolling | Monitoring page scrolling, such as scroll-up and scroll-down |
| #Mouse scroll on other pages | Total number of scroll events done on pages other than the landing page |
| #Mouse moves | Total number of mouse movement events, such as the number of left, center, and right mouse button clicks |
| #Mouse moves on other pages | Total number of scroll movements done on pages other than the landing page |
| Mouse movements | Monitoring the data of mouse movements, such as mouse right clicks, mouse double clicks, mouse movements, and area of the moved mouse |
| #Page views | Total number of pages viewed by the user |
| #Pages inlanguages | Total number of pages in the browser history |
| #Visits | Total number of visits to the ad web pages |
| Visit duration | Amount of time the user spends on the site |
| Execution efficiency | Client's JavaScript code execution time for a given task |
| User interest | Determine whether the user interest ratio is below a predefined threshold User Interest $=\frac{\text{no. of times Ads are visited by users >1 sec}}{\text{no. of clicks on Ads by users}}$ |
| Keystroke data | Monitoring the keys struck on a keyboard, such as the number of pressed keys and the number of switches between text fields on the page using the tab key |
| #Pasted word | Number of pasted words from the clipboard |
| #Text_field clicked | Number of text fields clicked |
| Filled form | Monitor form fill events, such as the number of controls in the form that must be filled, the number of fields replaced with new values in the controls, the number of texts changed while editing, the number of fields filled with no keys pushed, and the number of fields filled quickly |
| | Medium Features |
| Avg Len UA | Average user agent length |
| Avg Len referrer | Average referrer URL length |
| Agent | Phone/device models and types used by clickers |
| | |

Unique identifier of a given device agent to distinguish between phone and computer platforms

| Features | Descriptions |
|---|--|
| Unique agent | Distinct device agents |
| Unique agent at period T2 | In T2, the number of distinct devices related to the publisher at T2: first 15 min (0–14), second 15 min (15–9), third 15 min (30–44), last 15 min (45–9), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and days |
| Avg and STD of unique agent at period T1 | Average and standard deviation of the number of different devices for publishers at T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| Agent's ratio at T2 | Ratio of different devices to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| STD same agent T2 | Standard deviation of the number of clicks for different devices at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Max same agent T2 | Maximum number of clicks for different devices at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day. |
| Agent entropy T2 | Number of clicks entropy corresponding to different devices at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Agent entropy | Entropy of the click distribution on agent attribute |
| Avg #Clicks same agent | Number of clicks made by the same device agent; the average of this is then obtained. |
| Max #Clicks same agent | Number of clicks made by the same device agent; the maximum of this is then obtained. |
| Var #Clicks same agent | Number of clicks made by the same device agent; the variance of this is then obtained. |
| Skew #Clicks same agent | Number of clicks made by the same device agent; the skewness of this is then obtained. |
| Click fraction from UN/NA agent | Fraction of the number of clicks from the unknown/empty device model/agent used by the user to click |
| Agent-1 | Statistics for click data sorted by click time and agent as follows: Clicks are arranged by click time, followed by agents. Each click log row is then compared with the following click log row. If the device is the same, the current row is preserved; otherwise, it is eliminated. The filter row portion is then computed over the row total for each publisher. |
| Agent-2 | Statistics for click data sorted by agent only, calculated in the same way as Agent-1 (above feature) |
| Browser type | Names of the browsers used by the ad clickers |
| OS | |
| | OS version ID of the user's phone/computer |
| Web ID | OS version ID of the user's phone/computer A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with |
| | A unique identifier and a mechanism for Internet service providers and members to recognize |
| Web ID | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with |
| Web ID App ID | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement |
| Web ID App ID App price | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs |
| Web ID App ID App price Category ID | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and |
| Web ID App ID App price Category ID App popularity | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and its ratings |
| Web ID App ID App price Category ID App popularity Release date | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and its ratings Application launch date |
| Web ID App ID App price Category ID App popularity Release date Current version | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and its ratings Application launch date Current version number of the application Internet service provider for the user's connection |
| Web ID App ID App price Category ID App popularity Release date Current version ISP | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and its ratings Application launch date Current version number of the application Internet service provider for the user's connection Denotes whether the connected individual is a generator, distributor, or a user, as well as whether |
| Web ID App ID App price Category ID App popularity Release date Current version ISP Conn type | A unique identifier and a mechanism for Internet service providers and members to recognize who they are connecting with Unique identifier of a given application that contains an advertisement Price of the application that contains an advertisement A unique identifier of the category to which the application belongs Popularity of the application among users, from the number of times it has been downloaded and its ratings Application launch date Current version number of the application Internet service provider for the user's connection Denotes whether the connected individual is a generator, distributor, or a user, as well as whether the connection connects with the grid, a local network, or an embedded network |

| Features | Descriptions |
|--|--|
| Language | Information on the language of the agent, browser, or app |
| Session ID | A unique identifier for the session by the user |
| %Brand | Percentage of clicks coming from each agent brand (e.g., MAUI, Nokia, generic, Apple, Blackberry, Samsung, Sony, LG, and other brands) out of the total clicks for a particular publisher |
| UAgent frequency | User agent frequency at different time intervals |
| IP_Cookie frequency | Reveals the number of cookies in each IP address at different time intervals A cookie is a piece of data from a website that is stored within a web browser and can be accessed by the website later. |
| Max segment size | A Transmission Control Protocol (TCP) header option field parameter. |
| TCP window size | In each instance, determines the window size and frequency of appearance in synchronized packets during the TCP handshake |
| TCP window scale | A TCP header option field parameter typically used in conjunction with window size to assist in determining the OS type |
| NOP | The no-option (NOP) number is one byte in size and is used to fill the TCP options field in order to boost the packet length by a fourfold factor. Each operating system has its own set of TCP NOP settings. |
| Time to live | A timer value that tells the recipient how long to hold before discarding and expiring the packet A timer value that instructs the recipient how long to keep the packet until dismissing and expiring it |
| Port | Examine whether the click generator (human or bot) has a proclivity to use specific ports, such as TCP or User Datagram Protocol (UDP). |
| Avg App CvR | Average conversion rate of the app ID |
| Avg OS CvR | Average conversion rate of the OS ID |
| Avg agent CvR | Average conversion rate of the agent ID |
| Avg channel CvR | Average conversion rate of the channel ID |
| Unique IP&agent periods T2 | Number of different IPs + agents associated with the publisher at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Avg and STD of unique IP&agent at period T1 | Average and standard deviation of the number of different IPs + agents for publishers at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| IP&agent ratio at T2 | Ratio of different IPs + agents to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| STD same IP&agent T2 | Standard deviation of the number of clicks for different IPs + agents at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Max same IP&agent T1 | Maximum number of clicks for different IPs + agents at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| IP&agent entropy T2 | Number of clicks entropy corresponding to different IPs + agents at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| %Brand_clicks/#clicks | Percentage of clicks received by each brand divided by the total number of clicks produced by each publisher. |
| Avg and STD null agent | Average and standard deviation of the total clicks with null as agent that occurred every minute for a particular publisher |
| | IP Features |
| IP | IP addresses' clicks |

| | Table A2. Cont. |
|--|--|
| Features | Descriptions |
| Server IP | IP address of the ad server |
| Unique IP | Distinct IP addresses' clicks per publisher |
| Unique IP at different time intervals | Distinct IP addresses' clicks per publisher in 1 h and 10 h |
| Unique IP parts | Distinct parts of the IP addresses |
| Legitimacy of IP | Whether the originating IP address is on a blacklist |
| Unique IP at period T2 | Number of different IP addresses associated with the publisher at T2; T2: first_15 min (0–14), second_15 min (15–29), third_15 min (30–44), last_15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Avg and STD of unique IP at period T1 | Average and standard deviation of the number of different IP addresses for publishers at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| IPs' ratios at T2 | Ratio of different IP addresses to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| STD same IP T2 | Standard deviation of the number of clicks for different IP addresses at T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Max same IP T2 | Maximum number of clicks for various IP addresses at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| IP entropy T2 | Number of clicks entropy corresponding to different IP addresses at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| IP frequency | IP frequency at different time intervals |
| | Number of Clicks Features |
| #Clicks | Total number of clicks, count of rows in the click log. |
| #Clicks daily | Total number of clicks, count of rows in the click log on a daily basis |
| Click ID | A unique identifier for the ad click by the user |
| Avg and STD #Clicks in min | Average and standard deviation of the total clicks that occurred every minute for a particular publisher. |
| Avg and STD #Clicks in h | Average and standard deviation of the total clicks that occurred every minute for a particular publisher |
| Avg and STD #Clicks URL is null | Average and standard deviation of the total clicks produced by each publisher with null as a referrer that occurred every minute during the night, morning, afternoon, and evening |
| #Clicks same IP | Number of clicks originating from the same computer IP address |
| #Clicks unique IP | Number of clicks originating from different/unique computer IP addresses |
| IP only one | Whether an IP address has only one ad click |
| Avg IP CvR | Average conversion rate of an IP having #clicks |
| Max #Clicks same IP | Number of clicks originating from the same computer IP address; the maximum of this is then obtained. |
| Entropy #Clicks same IP | Number of clicks originating from the same computer IP address; the entropy of this is then obtained. |
| Var #Clicks same IP | Number of clicks originating from the same computer IP address; the variance of this is then obtained. |

| Features | Descriptions |
|--|--|
| Click ratio on advertiser, IP, cookie, agent, cid, ctry, referrer, Unique Ad-project, Unique Ad-position, and Unique agent | Click ratio for each #Clicks/#Advertisers, #Clicks/#IP, #Clicks/#cookie, #Clicks/#agent, #Clicks/#Cid, #Clicks/#Country, #Clicks/#Referrer, #Clicks/# Unique Ad-project, #Clicks/# Unique Ad-position, and #Clicks/# Unique Ad-agent |
| Click per ad, device, ctry, and referrer ratio | Percentage of the number of clicks per ad, device, and country |
| Suspicious click ratio | Percentage of the duration of suspicious clicks per publisher |
| #Clicks in channel | Total number of clicks produced by each publisher across all channels |
| %Ctry_clicks/#clicks | Percentage of clicks from every country divided by the total number of clicks produced by each publisher |
| Avg and std null referrer | Average and standard deviation of the total clicks with null as the referrer URL that happened for a particular publisher in every minute |
| #Click IP&Hour&Day | Total number of clicks grouped by IP address, day, and hour of the click |
| #Click IP&App | Total number of clicks grouped by IP address and app ID of the click |
| #Click IP&App&OS | Total number of clicks grouped by IP address, OS, and app ID of the click |
| Var click day by IP&App&Channel | Variance in click days for an IP, app, and channel |
| | Provider/Advertiser/Ad Features |
| Publisher ID | Unique identifier of the particular publisher of an advertisement campaign |
| Campaign ID | Unique identifier of a given advertisement campaign |
| Ad ID | Unique identifier of a given advertisement for all commercial assets |
| #Cid | Total number of campaign IDs associated with the clicks received by each publisher |
| Cid entropy | Entropy of the click distribution on campaign IDs |
| Cid/click ratio | Average percentage of the number of clicks for each campaign |
| Unique Cid | Distinct number of campaign IDs |
| Max #Clicks same Cid | Number of clicks received by the same campaign ID; the maximum of this is then obtained. |
| Var #Clicks same Cid | Number of clicks received by the same campaign ID; the variance of this is then obtained. |
| Skew #Clicks same Cid | Number of clicks received by the same campaign ID; the skewness of this is then obtained. |
| Publisher address | Mailing address of the publisher |
| Publisher account | Bank account associated with the publisher |
| Publisher's reputation | Whether the click occurs from an untrustworthy website |
| Visibility of ad controls | Determine whether the ad is clearly visible on the screen and not hidden behind a button or is off-screen |
| Size of ad control | Determine whether an ad is too small on the screen, making it difficult for users to read or locate it |
| Misplace of Ad-control on tiny screen | Examine to verify that the distance between an ad control and a clickable non-ad item is less than a certain threshold |
| Unique ad project | Number of unique ad projects |
| Unique ad position | Number of unique ad positions |
| Publisher frequency | Publisher ID frequency at different time intervals |
| | Other Features |
| Channel ID | Unique identifier of a given ad publisher |

| Features | Descriptions |
|---|--|
| Channel | Channel type of the publisher, which includes ad: adult sites, co: community, es: entertainment and lifestyle, gd: glamour and dating, in: information, mc: mobile content, pp: premium portal, and se: search and portals and services. |
| Referred URL | The URL referrer's web page that contains the ad content |
| #Referrer | Total number of URL referrers from which every publisher received clicks |
| Unique referrer | Distinct URL referrers |
| Channel_Prior | Prior fraud probability in each category |
| Referrer/click ratio | Average click ratio for each referrer URL |
| Non-referrer/click ratio | Total number of non-referred URL clicks with respect to the total clicks received for each publisher |
| Click fraction from UN/NA referrer | Fraction of the number of clicks from unknown/empty referrer URLs |
| Developer ID | Unique identifier of a given developer who developed the app that contained the advertisement |
| #Apps | Number of apps developed by the same developer |
| Avg app rating | Average rating of the app by users |
| Avg app versions | Average number of versions of the application |
| Avg pos_reviews | Average rate of positive reviews and helpfulness of the application |
| %Free apps | Percentage of free apps developed by the same developer |
| No. of ad controls | Recognize the number of ads displayed on the screen; it must be one ad per phone screen and three ads per tablet screen at most. |
| App down ratio | Ratio of app downloads per publisher |
| Is attributed | Target class of prediction, indicating whether the action was done after clicking |
| Is clicked | Target class of prediction, indicating whether the ad was clicked |
| Status | Status that describes the click's legitimacy (benign/fraud) |
| Fingerprint | An identification based on the JavaScript language parameters accessible in the browser |
| Store markdown | Difference between a product's initial and current prices |
| #Successful transactions | Amount of goods exchanged after the seller has delivered the goods and the buyer has validated receipt of the goods |
| Deposit | Margin offered to the Taobao platform by the online retailer |
| Dynamic score | A careful examination of the store based on three criteria: commodity quality, service attitude, and logistical service |
| Number of additional reviews | Number of reviews written by purchasers after they have used a product or service for a length of time |
| Collection conversion rate | Ratio of the number of successful transactions of major goods in a store to the number of collections throughout time |
| Avg reputation score | A shop's reputation score during the period of its operation |
| Rate of reviews with pictures | Number of reviews with photos divided by the total number of reviews for the store |
| Rate of additional reviews | Number of added reviews divided by all of the store's reviews |
| Collection conversion rate of secondary goods | Ratio of secondary products sales at a store to the number of collections over time |
| Operating duration | Length of time the store has been operating since its formation |
| Reputation level | A store's reputation level over the period of its operation |
| Favorable rating | When visitors have a positive opinion or reaction to something, it means that they agree with it and appreciate it. |

| Features | Descriptions |
|---|---|
| Site ID | A unique identification number assigned by the ministry to a site listed in the site registry |
| Site cat | The category to which the site belongs, such as e-commerce |
| App cat | The category to which the app belongs, such as entertainment |
| App dom | A method used within the common language infrastructure to isolate running software applications so that they do not interfere with one another |
| Age | Age of the Internet user who clicked on the ad |
| Gender | Gender of the Internet user who clicked on the ad |
| Income | Income of the Internet user who clicked on the ad |
| Daily Internet usage | Daily Internet consumption of the user |
| Daily time | Duration of time a user spends on the Internet on a daily basis |
| Unique Cid at period T2 | Number of different campaign IDs associated with the publisher at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Avg and STD of unique Cid at period T1 | Average and standard deviation of the number of different campaign IDs for publishers at T1; T1: per min, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| Cids' ratio at T2 | Ratio of different campaign IDs to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| STD same Cid T2 | Standard deviation of the number of clicks for different campaign IDs at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Max same Cid T1 | Maximum number of clicks for different campaign IDs at T1; T1: per minute, 5 min, 15 min, 1 h, 3 h, 6 h, and 1 day |
| Cid entropy T2 | Number of clicks entropy corresponding to different campaign IDs at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Unique referred periods T2 | Number of different referred URLs associated with the publisher at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Avg and std of unique referred at period T1 | Average and standard deviation of the number of different referred URLs for publishers at T1; T1: per minute, 5 min, 15 min, hour, 3 h, 6 h, and 1 day |
| Referred ratio at T2 | Ratio of different referred URLs to clicks at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| STD same referred T2 | Standard deviation of the number of clicks for different referred URLs at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| Max same referred T1 | Maximum number of clicks for different referred URLs at T1; T1: per minute, 5 min, 15 min, hour 3 h, 6 h, and 1 day |
| Referred entropy T2 | Number of clicks entropy corresponding to different referred URLs at T2; T2: first 15 min (0–14), second 15 min (15–29), third 15 min (30–44), last 15 min (45–59), night (0:00–5:59), morning (6:00–11:59), afternoon (12–17:59), evening (18:00–23:59), and 3 days |
| #Axis APIs | Number of APIs for determining the actual click coordinates generated by users |
| #View-size APIs | Number of APIs for determining the size of an ad view; acquiring the size of an ad view in order to position the coordinates of the false click within the ad view |
| #Rand num APIs | Number of APIs for generating random numbers |
| DDG size | Size of the data dependence graph (DDG); the larger the size of the DDG, the more the data have been processed, indicating fraudulent behavior |

| Features | Descriptions |
|--|---|
| Rand condition | Random numbers in condition expression |
| Node roles | Identifying exploited servers by nodes, especially those with URLs that do not follow well-known advertising URL patterns Each URL discovered during data crawling is referred to as a node. |
| Node domain regs | Determine node domain registration times, as most malware domains expire within a year after registration Each URL discovered during data crawling is referred to as a node. |
| Node frequency | The popularity and reliability of node domains are measured; recognize each node's domain and calculate the number of distinct publishers linked to this domain every day. Each URL discovered during data crawling is referred to as a node. |
| Node pair frequency | Analyze the frequency of two adjacent nodes on ad paths Each URL discovered during data crawling is referred to as a node. |
| Cookie frequency | Cookie frequency at different time intervals A cookie is a piece of data from a website that is stored within a web browser and can be accessed by the website later. |
| Born cookie | The time the cookie was generated A cookie is a piece of data from a website that is stored within a web browser and can be accessed by the website later. |
| #Peer nodes | Number of peer nodes, derived from raw traffic information Peers are other nodes that operate in the same manner as the nodes in the network. |
| #Packets | Number of packets transmitted through the network |
| #Bytes | Sum of the number of bytes for all the packets transmitted through the network |
| #Flows | Number of flows made over the network |
| Max, min, med, mean, var, and STD of flows in packets | Maximum, minimum, median, mean, variance, and standard deviation of the number of packets in each flow |
| Max, min, med, mean, var, and STD of bytes in flow | Maximum, minimum, median, mean, variance, and standard deviation of the number of bytes in each flow |
| Max, min, med, mean, var, and STD of bytes in flow duration | Maximum, minimum, median, mean, variance, and standard deviation of the number of bytes in each flow duration |
| Max, min, med, mean, var, and STD of application layer protocol fields | Maximum, minimum, median, mean, variance, and standard deviation of the number of unique method types, number of unique hosts and URLs and their corresponding numbers of packets and bytes in HTTP requests, and number of unique server names appearing in the TLS client hello and their corresponding numbers of packets and bytes |
| 1 norm | Maximum value of the absolute values for every column in the signals' matrix Note: This value was determined using the signals provided by the mobile phone's sensors. |
| Infinity norm | Maximum value of the absolute values for each row in the signals' matrix Note: This value was determined using the signals provided by the mobile phone's sensors. |
| Fresenius norm | Square root of the sum of squares of all the elements in the signals' matrix Note: This value was determined using the signals provided by the mobile phone's sensors. |
| Max, min, RMS, RMSE, mean, PNum, TNum, SMA, skew, kurt, ATP, and ATT | Maximum value, minimum value, root mean square value, root mean square error, average value of each tap, number of local peaks, number of local troughs, signal magnitude area, asymmetry of the curve, peakedness of the curve, average time to a peak, and average time to a trough of the time-domain signal in each dimension. Note: These values were determined using the signals provided by the mobile phone's sensors. |
| Amplitude spectrum | A power spectrum's square root, which is used to define broadband signals and disturbances. Note: This value was determined using the signals provided by the mobile phone's sensors. |
| Power spectrum | Describes the distribution of power into frequency elements that make up the signal. Note: This value was determined using the signals provided by the mobile phone's sensors. |
| Formant of the signal spectrum | Commonly used to describe the wide peak or the local maximum in a spectrum |
