Abstract: Symbiosis between insects and fungi arose multiple times during the evolution of both groups, and some of the most biologically diverse and economically important are mutualisms in which the insects cultivate and feed on fungi. Among these are bark beetles, whose ascomycetous cultivars are better known and studied than their frequently-overlooked and poorly understood basidiomycetous partners. In this study, we propose five new species of *Entomocorticium*, fungal mutualists in the Russulales (*Basidiomycota*) that are mutualistic symbionts of scolytine beetles. We have isolated these fungi from the beetle mycangia, which are structures adapted for the selective storage and transportation of fungal mutualists. Herein, we present the most complete phylogeny of the closely related genera *Entomocorticium* and *Peniophora* and provide insights into how an insect-associated taxon (*Entomocorticium*) evolved from within a wood-decaying, wind-dispersed lineage (*Peniophora*). Our results indicate that following a transition from angiosperms to gymnosperms, fungal domestication by beetles facilitated the evolution and diversification of *Entomocorticium*. We additionally propose four new species: *Entomocorticium fibulatum* Araújo, Li & Hulcr, sp. nov.; *E. belizense* Araújo, Li & Hulcr, sp. nov.; *E. perryae* Araújo, Li & Hulcr, sp. nov.; and *E. macrovesiculatum* Araújo, Li, Six & Hulcr, sp. nov. Our findings highlight the fact that insect-fungi associations remain an understudied field and that these associations harbor a large reservoir of novel fungal species.

Keywords: wood-decaying fungi; *Russulales*; *Peniophoraceae*; mutualism; new species

1. Introduction

Several insect groups within ants, termites, wasps, and beetles have independently evolved mutualisms with a variety of fungal lineages that help them extract nutrients from wood, an otherwise intractable substrate [1–3]. In many of these associations, the

insects are true fungus farmers, i.e., they inoculate their fungal symbionts into the substrate and cultivate them to feed their progeny, and therefore, the fungal symbionts have become domesticated crops [4,5]. Many of these insect-cultivated fungi have evolved nutrient-provisioning adaptations and have become dependent on their partner insects for dispersal [4]. Many of these insects, including beetles, have evolved specific, highly evolved organs (mycangia) to maintain and transport their symbiotic fungi [6–8]. Unfortunately, fungal mutualists have thus far been studied in fewer than 5% of all bark beetles [5].

The most well-known fungi found living mutualistically with Scolytinae beetles are species within *Ophiostomatales* (*Ascomycota*). However, because these are often targeted in surveys of bark beetle fungi, a dearth of knowledge exists on other potential fungal mutualists. Surprisingly, this even includes important pest species. For example, the southern pine beetle (SPB), *Dendroctonus frontalis* (Curculionidae, Scolytinae, Hylurgini) is the most economically important pest in pine plantations across the Southern USA and Central America [9]. The biology, ecology and management of this beetle have been extensively investigated [9–11]. The southern pine beetle has also served as a model system for understanding symbiotic interactions between beetles and fungi [12,13]. Despite these previous investigations of symbiotic associations with *D. frontalis*, the diversity and evolutionary history of its most beneficial fungal associate—an *Entomocorticium* species (Russulaceae, Russulales, Basidiomycota)—remains obscure.

The genus *Entomocorticium* is currently comprised of eight species, all associated with Scolytinae beetles [14,15]. *Entomocorticium dendroctoni*, the type species of *Entomocorticium* [14], was described based exclusively on morphological features to accommodate a cryptic fungus that was observed growing intermingled with a blue stain fungus [14]. According to the original description, the fungus produced abundant sessile basidiospores in the galleries and pupal chambers of the mountain pine bark beetle *D. ponderosae* (mountain pine beetle) in *Pinus contorta* (lodgepole pine) [14].

The nutritional symbioses with *Entomocorticium* are only known for a few beetle species thus far [15,16]. Some of these beetles use mycangia to carry their *Entomocorticium* partners from tree to tree. Within the genus *Dendroctonus* (Curculionidae, Scolytinae, Hylurgini), some of the main documented vectors of *Entomocorticium* fungi, there are two clades of beetles with independent origins of mycangia [17,18]. One clade contains *D. ponderosae* and *D. jeffreyi*, which possess maxillary mycangia (located in the maxillae, the segmented mouthparts) wherein they carry obligate *Ophiostomatales* mutualist fungi [19]. These beetles appear to have loose associations with multiple *Entomocorticium* species that have not previously been found to be transported in mycangia. They are occasionally found in the beetle's pupal chambers but how the fungi are disseminated is unknown [20]. The second clade of beetles, which includes *D. frontalis*, *D. brevicomis*, and several other species, all possess prothoracic mycangia (a tube in the inner wall of the pronotum) [21,22]. Some of these bark beetles carry *Entomocorticium* in their mycangia and for at least two, *D. frontalis* and *D. brevicomis*, the fungi are obligate nutritional mutualists. However, the fungal symbionts are unknown for many of these beetles.

Two other genera of pine beetles, only distantly related to *Dendroctonus*, are also known to be associated with *Entomocorticium*. A twig beetle, *Pityoborus comatus* (Curculionidae, Scolytinae, Corthylini), carries an *Entomocorticium* sp. in large, pubescent impressions on the sides of its prothorax that function as a mycangium [23]. *Ips avulsus* (Curculionidae, Scolytinae, Ipini) is also commonly found with an *Entomocorticium* species but how it is disseminated is not known and the presence of mycangia or other spore carrying-structures have not been investigated for this beetle [24].

Remarkably, the diversity of this important group of fungi remained uncharacterized until the early 2000s. Hsiau & Harrington (2003) were the first to show that *Entomocorticium* was a diverse fungal lineage associated solely with a group of phloem-inhabiting bark beetles that feed heavily on fungi. In addition to *E. dendroctoni*, they identified nine putative species based on their mt-SSU, ITS and IGS-1 analyses. Hsiau & Harrington [16] also suggested that the *Entomocorticium* clade was relatively young, likely having been recently

derived from *Peniophora*, a genus of resupinate wood decay fungi that colonize several plant families and that rely exclusively on the wind to disperse their spores. A more recent study described seven of Hsiao & Harrington's nine putative species of *Entomocorticium* based on morphology and molecular data from the ITS and 28S rDNA [15]. Unfortunately, no studies to date have addressed the broader evolutionary picture regarding the ecological relationships between the genera *Peniophora* and *Entomocorticium* as well as the context in which their associations with the beetle vectors and host trees might have occurred.

In this study, we propose five new species belonging to the genus *Entomocorticium* and explore the diversity and evolutionary relationships of this fungal lineage with their beetle vectors and tree hosts. In order to investigate possible evolutionary scenarios, we have built a comprehensive phylogeny based on all available data from the genera *Peniophora* (54 species) and *Entomocorticium* (13 named species, including those proposed herein) and three putative species. We tested whether *Entomocorticium* is a distinct, monophyletic genus within the order *Russulales* and what factors promoted its differentiation from the genus *Peniophora*. In terms of ecology and evolution, we investigated the beetle host spectrum across the *Entomocorticium* phylogeny and provide a hypothesis on how the association between gymnosperms, angiosperms and beetles influenced the rise of these fungal mutualists.

2. Material and Methods

2.1. Fungus Isolation

The fungi used in this study were isolated from pronotal mycangia of adult bark beetles *Dendroctonus brevicomis*, *D. frontalis*, and *Pityoborus comatus*, in the USA (California, Colorado, Florida, Louisiana, Montana, Michigan, New Mexico, South Carolina, Texas and Utah) (see [25]) and Belize (Table 1). Isolates of *Entomocorticium fibulatum* and *E. belizense* were conducted for this study, while the isolation of *E. perryae* and *E. macrovesiculatum* was previously conducted by Bracewell and Six [25]. Beetles were identified using external morphology with identification keys and images [26–28]. Whole beetles were surface-washed by vortexing for 1 min in 1 mL of sterile distilled water with one small drop of Tween detergent. Pronota of adult beetles were removed and crushed in a 500 µL of sterile phosphate buffer saline and vortexed for 30 s. The resulting solutions were diluted to 1:100 and 1:1000 concentrations, and each dilution was used to inoculate potato dextrose agar (PDA; Becton, Dickinson and Company, MD, USA) plates. Fungi were allowed to grow at 25 °C for 5–10 d. Representative isolates of different fungal morphotypes were placed onto new 2% potato dextrose agar (PDA) plates to obtain pure cultures and these were retained for molecular identification. In addition, we attempted to induce the production of the sexual stage by plating the isolates in Malt agar and also inoculating them in pinewood chips, but these efforts failed to promote the production of the sexual stage in all our isolates. Axenic cultures of the fungi are deposited in the culture collection (CMW) of the Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria, South Africa and in the Westerdijk Fungal Biodiversity Institute collections (CBS). Beetle remains of specimens collected in Belize or Florida were vouchered the UF Forest Entomology (UFFE) cryo-collection.

2.2. Morphological Observations

To access the micro-morphological features, we collected small samples of each isolate in 3–5 parts across the plate, i.e., edge, intermediate portion and center. These fungal pieces were mounted in 4% lactic acid or lacto-fuchsin and observed under an optical microscope (Zeiss Axioscope 5). Measurement of taxonomically relevant structures, e.g., vesicles and chlamydospores, were performed using the Zen software (Zeiss, Jena, Germany). The semi-permanent slides were sealed with nail polished by direct application of at least 3 layers around the cover slip edges and stored in a slide box for further observation.

2.3. Taxa Sampling and Sources

In order to test the relationship of *Entomocorticium* species with other genera within the order *Russulales*, we built a comprehensive phylogeny based on LSU and ITS sequences from [29,30] (Supplementary Figure S1 and Table S1). Once we established the relationship between *Entomocorticium* and *Peniophora*, we performed a second analysis including five loci, (SSU, LSU, *TEF*, ITS and IGS) consisting of 129 taxa from *Peniophora* and *Entomocorticium* species and four outgroup taxa (*Dichostereum* spp.). Sequences in the analysis included those from our isolates as well as *Peniophora* and *Entomocorticium* sequences archived in GenBank. However, the majority of taxa of our dataset (78 out of 138) were composed of only ITS and LSU rDNA due to limited data availability in GenBank for this fungal group (Table 2). As a quality control approach to confirm the identity of sequences used in this study, we subjected all sequences, including newly generated sequences of *Entomocorticium* from beetle mycangia (Table 2) to a BLAST comparison with reliable ex-types.

Table 2. Species used in the *Russulales* analyses and their GenBank accession numbers.

(17 spp.) to date. Our phylogenetic reconstruction corroborates previous studies connecting both fungal genera [15,16] (Figure 1).

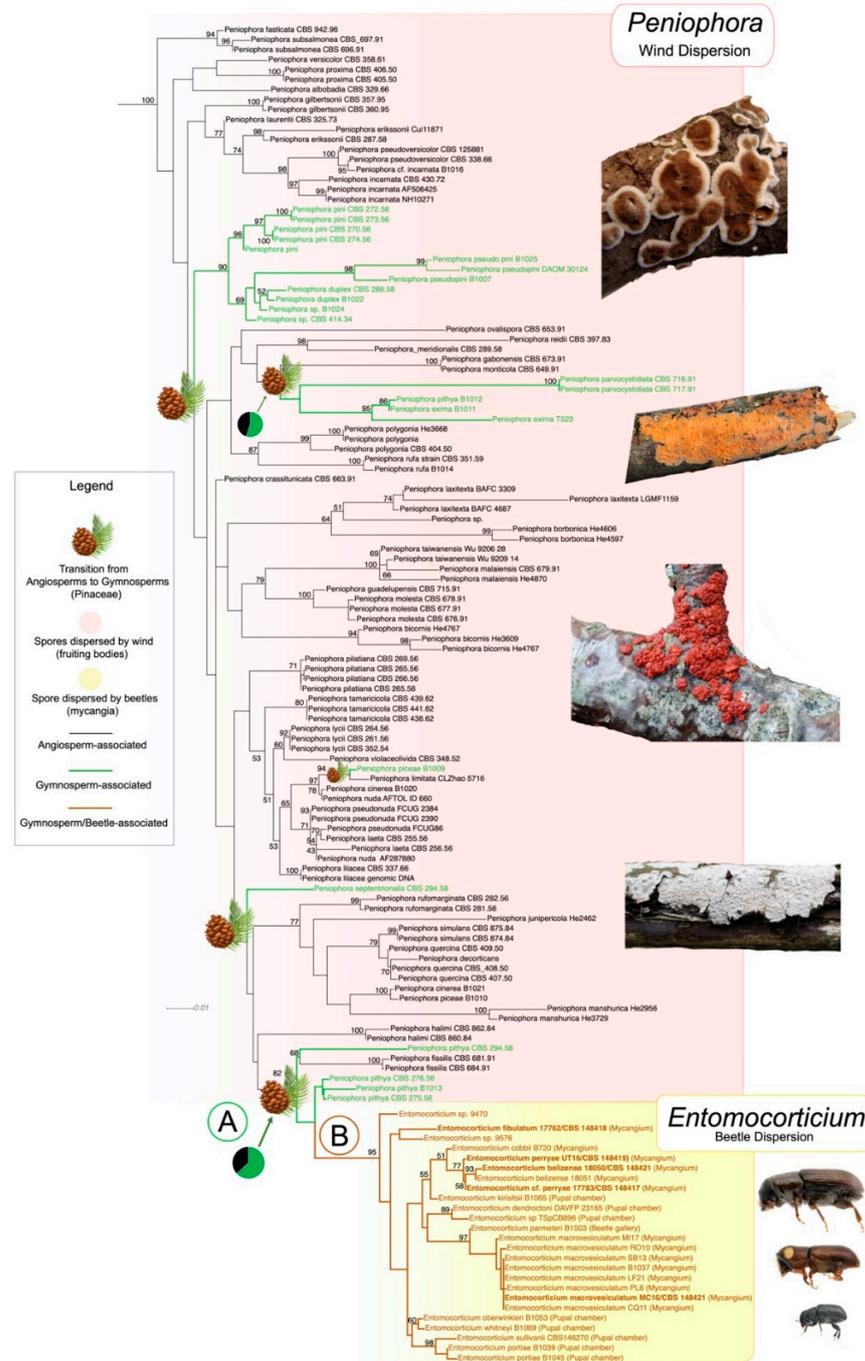

Figure 1. Maximum likelihood tree showing *Peniophora*/*Entomocorticium* clade obtained from RAxML analyses with a concatenated dataset of 5-loci (SSU, LSU, TEF, ITS and IGS). Ancestral Character State Reconstructions (ACSR) analyses based on fungal association with their plant hosts. Black branches mean association with angiosperms, green indicate an association with gymnosperms and no association with beetles, brown indicates association with gymnosperms and beetles. Pinecones indicate a transition from angiosperms to gymnosperms. Node A indicates the transition from angiosperms to gymnosperms and the origin of *Entomocorticium*, node B indicates fungal radiation following the association of *Entomocorticium* with bark beetles. Photos by Patrick Harvey, Jerzy Opiola, Eva Skific and Andrew Johnson.

We describe an evolutionary switch from fungi with relatively complex basidiocarps that are strictly wind-dispersed (*Peniophora*) to fungi with minimal or unknown reproductive structures that are actively dispersed within beetle mycangia (*Entomocorticium*). Our ancestral character state reconstruction (ACSR) indicates that *Peniophora* is ancestrally associated with angiosperms but has transitioned to gymnosperms at least five times. Among the 54 species of *Peniophora* included in this study, only nine are associated with gymnosperms, i.e., *Peniophora duplex*, *P. exima*, *P. parvocistidiata*, *P. piceae*, *P. pini*, *P. pseudonuda*, *P. pseudo-pini*, *P. pithya* and *P. septentrionalis* (Figure 1, green branches). Our results indicate that following one of these transitions from angiosperms to gymnosperms (Figure 1, Node A), fungal domestication by bark beetles facilitated the evolution of *Entomocorticium* (Figure 1, Node B). Our data suggest that the domestication of these fungi by beetles might have promoted speciation and dissemination of this new fungal lineage across at least five beetle lineages. Currently, we have records for six beetle species associated with *Entomocorticium* (five shown in Figure 2), which might represent at least three independent origins (beetle genera) of *Entomocorticium* farming and multiple vector switches within those beetle groups.

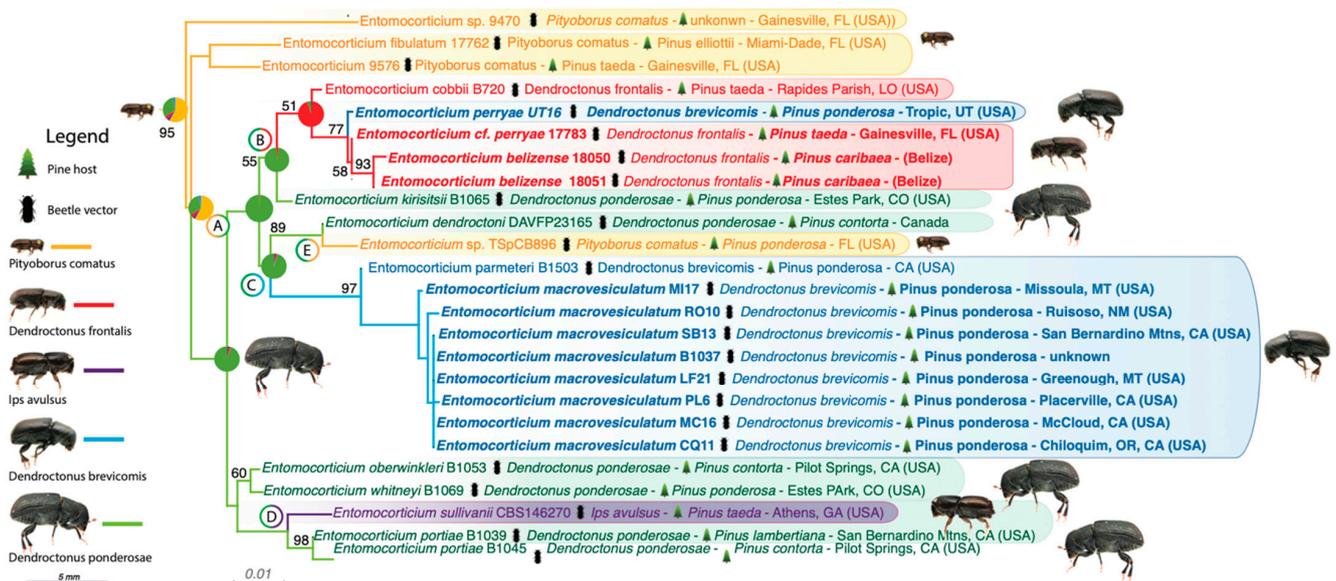

Figure 2. Close-up of the *Entomocorticium* clade showed in Figure 1. Character-state reconstruction of the association of *Entomocorticium* spp. with beetle vectors. Branch and boxes color mean: Yellow = *Pityoborus comatus*; Red = *Dendroctonus frontalis*; Blue = *D. brevicomis*; Green = *D. ponderosae*; Purple = *Ips avulsus*. Node A indicates transition from *Pityoborus comatus* to *Dendroctonus ponderosae*, node B from *D. ponderosae* to *D. frontalis*, node C from *D. ponderosae* to *D. brevicomis*, node D from *D. ponderosae* to *Ips avulsus* and node E from *D. ponderosae* back to *P. comatus*. Scale bar is in relation to the beetle sizes = 5 mm. Beetle photos by Andrew Johnson.

With the current state of sampling of *Entomocorticium* we investigated the radiation of the genus with its beetle vectors. Our analysis, considering the beetle vector associations, suggests that the first beetle lineage to have domesticated an ancestor of the genus *Entomocorticium* was likely the twig beetles in *Pityoborus* (ACSR = 58%; Figure 2). After that, a transition from twig beetles to *D. ponderosae* appears to have occurred relatively soon after the initial domestication. Interestingly, *Entomocorticium* spp. found with *D. ponderosae* are not consistent, never carried in mycangia, and any association with the beetle is, therefore, most likely facultative and co-evolution is not expected. There were at least four switches after acquisition by *D. ponderosae* to other beetles, including *D. frontalis* (Figure 2 node B, ACSR = 95%) and *D. brevicomis* (Figure 2 node C, ACSR = 94%) and to other beetle genera, i.e., *Ips avulsus* (Figure 2, node D, ACSR = 88%), and a re-association with *Pityoborus* (Figure 2, node E, ACSR = 99%).

Taxonomy

Prior to this work, the genus *Entomocorticium* was comprised of eight species: *E. dendroctoni*, *E. cobbii*, *E. kirisitsii*, *E. parmeteri*, *E. oberwinkleri*, *E. whitneyi*, *E. sullivanii* and *E. portiae* [14,15]. Distinct lineages in *Entomocorticium* can be recognized using a combination of morphology, distribution, vector-host associations and molecular markers (see Supplementary Table S2 showing inter and intraspecific genetic variation across in *Entomocorticium*). The topology of our multi-loci phylogenetic analyses revealed distinct fungal lineages associated with distinct beetle vectors and *Pinus* (Figure 2). We propose five new species of *Entomocorticium* based on all these traits combined. These new species were isolated from mycangia of *D. brevicomis*, *D. frontalis* and *Pityoborus comatus* inhabiting *Pinus ponderosa*, *P. caribaea*, *P. taeda* and *P. elliottii* in several USA states and Belize. Several additional lineages were found which are likely to be new taxa but were not described because we were unable to revive live cultures for obtaining morphology and depositing type material.

Entomocorticium fibulatum J.P.M. Araújo, Y. Li & J. Hulcr, sp. nov.—MycoBank MB 839833; Figure 3.

Etymology. The species epithet is derived from *fibula* (L. adj. f., with clamp) and refers to the abundant presence of clamp connections throughout the mycelium.

Typus. USA, Miami-Dade-FL, from *Pityoborus comatus* mycangium, 15 July 2015, J. Skelton, Y. Li & J. Hulcr (holotype FLAS-F-68307 (dried culture), ex-type CBS 148418 (live culture)).

Diagnosis. Fungus associated within *Pityoborus comatus* mycangium, inhabiting *Pinus elliottii*. Sterile hyphae exhibit abundant clamp connections throughout the mycelium.

Sexual morph not observed. *Asexual morph* is composed of sterile mycelium, simple or sparsely branched hyphae that are 2.1–5.8 µm wide, septate, with anastomosing hyphae and abundant clamp connections. *Hyphae* cylindrical, hyaline, sub-hyaline, forming thin-walled chlamydospore structures averaging 8 × 6 µm. *Aleurioconidia* not observed. Mycelial mat in culture regular, circular, pale brown becoming darker brown with age, slightly fimbriate, velvety, growing within and on the media.

Vector—*Pityoborus comatus* (Coleoptera, Curculionidae), Voucher UFFE: 28951.

Host—*Pinus elliottii* (Pinales, Pinaceae)

Distribution—Only recorded from Miami-Dade, FL (USA).

Entomocorticium perryae Araújo, Li, Six & Hulcr, sp. nov.—MycoBank MB 839834; Figure 4.

Etymology. Named after Thelma Perry, a pioneering African American female mycology technician responsible for the first description of mycangia in *Dendroctonus frontalis* and the first to report a basidiomycete from a scolytine mycangium.

Typus. USA, Tropic-UT, from *Dendroctonus brevicomis* mycangium, 5 July 2015, D. Six (holotype FLAS-F-68308, ex-type CBS 148419).

Diagnosis. The fungus associated with *Dendroctonus brevicomis* inhabiting *Pinus ponderosa*. Chlamydospores av. 6–11 × 8–13 µm.

Sexual morph not observed. *Asexual morph* is composed of sterile, simple, or sparsely branched hyphae that are 1.5–5 µm wide and regular or irregularly septate, clamp connections rare. *Hyphae* cylindrical and uniform, forming thin-walled chlamydospores of 6–11 × 8.2–13.5 µm. *Aleurioconidia* absent. *Cultures* floccose to dense and felty, circular, white becoming light grey to brown with age, fimbriate margin, growing within and on the media.

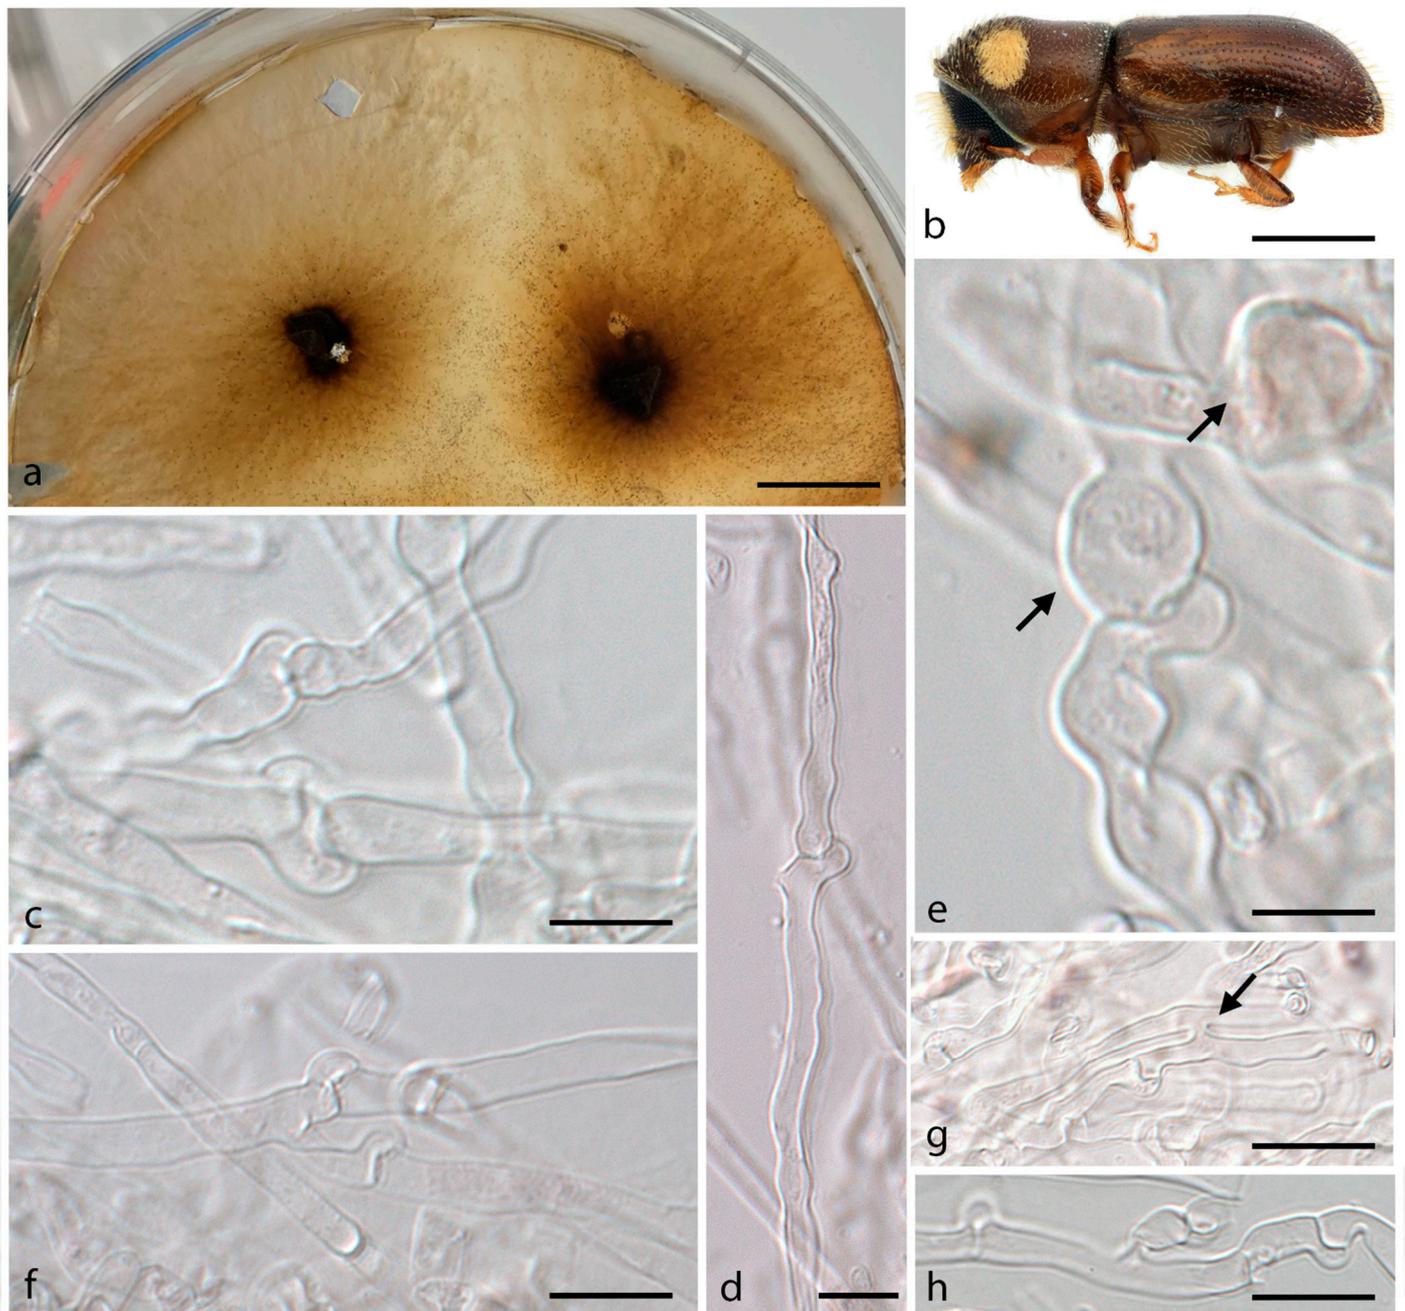

Figure 3. *Entomocorticium fibulatum*. (a) Culture aspect on PDA plate; (b) The beetle vector *Pityoborus comatus*; (c,d) Clamp connections; (e) Early stage of chlamydospores formed by a clamp connection (arrows); (f) Clamp connections; (g) Hyphae anastomosing (arrow); (h) Hypha exhibiting regular clamp connections. Scale bars: (a) = 2 cm; (b) = 0.5 cm; (c,d) = 4 μm ; (e–h) = 5 μm .

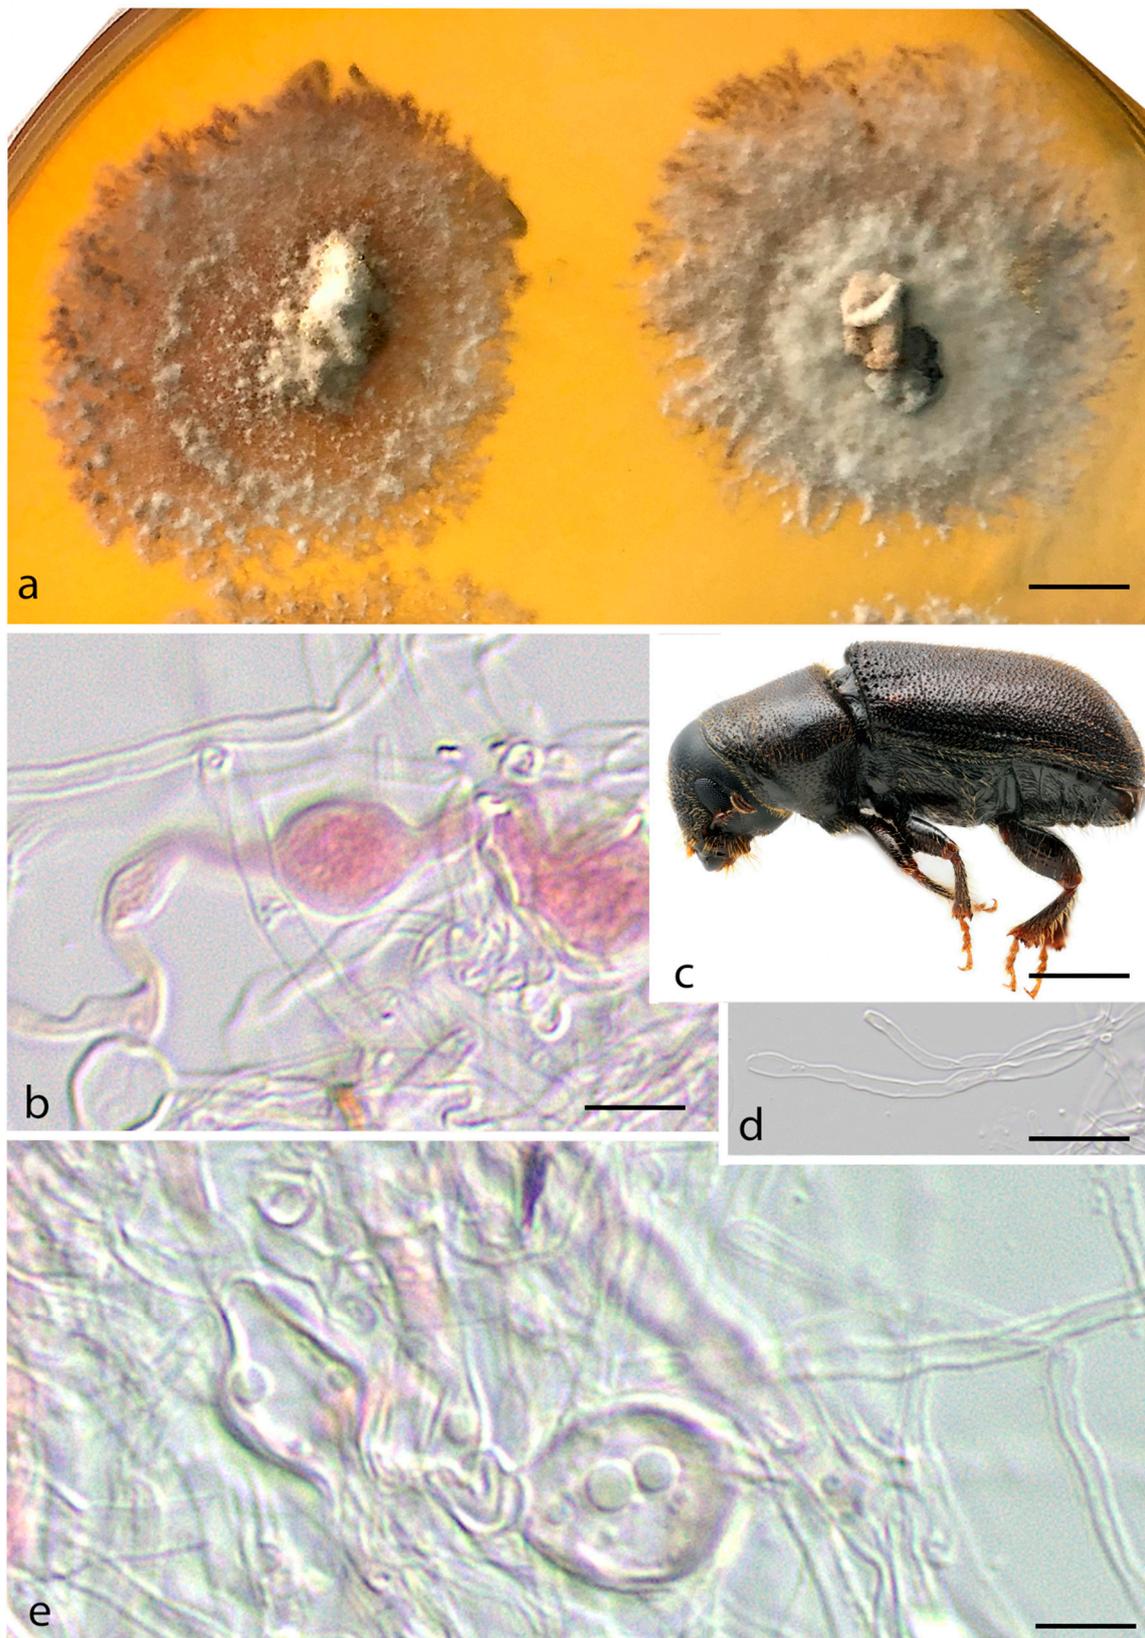

Figure 4. *Entomocorticium perryae*. (a) Culture aspect on PDA plate; (b) Chlamydospore in formation; (c) *Dendroctonus brevicornis* (vector); (d) Apical hyphae; (e) Chlamydospore. Scale bars: (a) = 1 cm; (b) = 5 μm ; (c) = 2 mm; (d,e) = 5 μm .

Vector—*Dendroctonus brevicomis* (Coleoptera, Curculionidae)

Host—*Pinus ponderosa* (Pinales, Pinaceae)

Distribution—Only recorded from Tropic, UT (USA).

Additional specimen examined: USA, Gainesville-FL, from *Dendroctonus frontalis* mycangium, 15 July 2019, J. Skelton, (FLAS-F-68306, CBS 148417 (live culture)) (as *E. cf. perryae* 17783): Fungus associated within *Dendroctonus frontalis* mycangium, inhabiting *Pinus taeda*. Sterile hyphae exhibit swollen hyphae, morphologically resembling those of ambrosial fungi by its clavate to globose cells that are usually irregular in size. Asexual morph composed of sterile, simple or branched, irregularly swollen, irregularly swollen hyphae, av. 2–5 μm width, regularly septate, clamp connections present but rare, chlamydospores absent. *Aleurioconidia* absent. Mycelial mat homogeneous, circular, light brown becoming darker with age, effuse, aerial hyphae scarce, with hyphae growing within the media.

Vector. *Dendroctonus frontalis* (Coleoptera, Curculionidae), Voucher UFFE:29184.

Host. *Pinus taeda* (Pinales, Pinaceae).

Distribution. Only recorded from Gainesville, FL (USA).

Note: Although we suspect that *Entomocorticium cf. perryae* (17783—Figure 2) is a distinct species, based on the host and vector association, we decided to take a conservative approach and include it within *E. perryae* in this study due to the very high genetic similarity (see Supplementary Table S2) and lack of morphological features. Future studies including more *E. perryae* specimens will elucidate this question.

Entomocorticium belizense Araújo, Li & Hulcr, sp. nov.—MycoBank MB 839835; Figure 5.

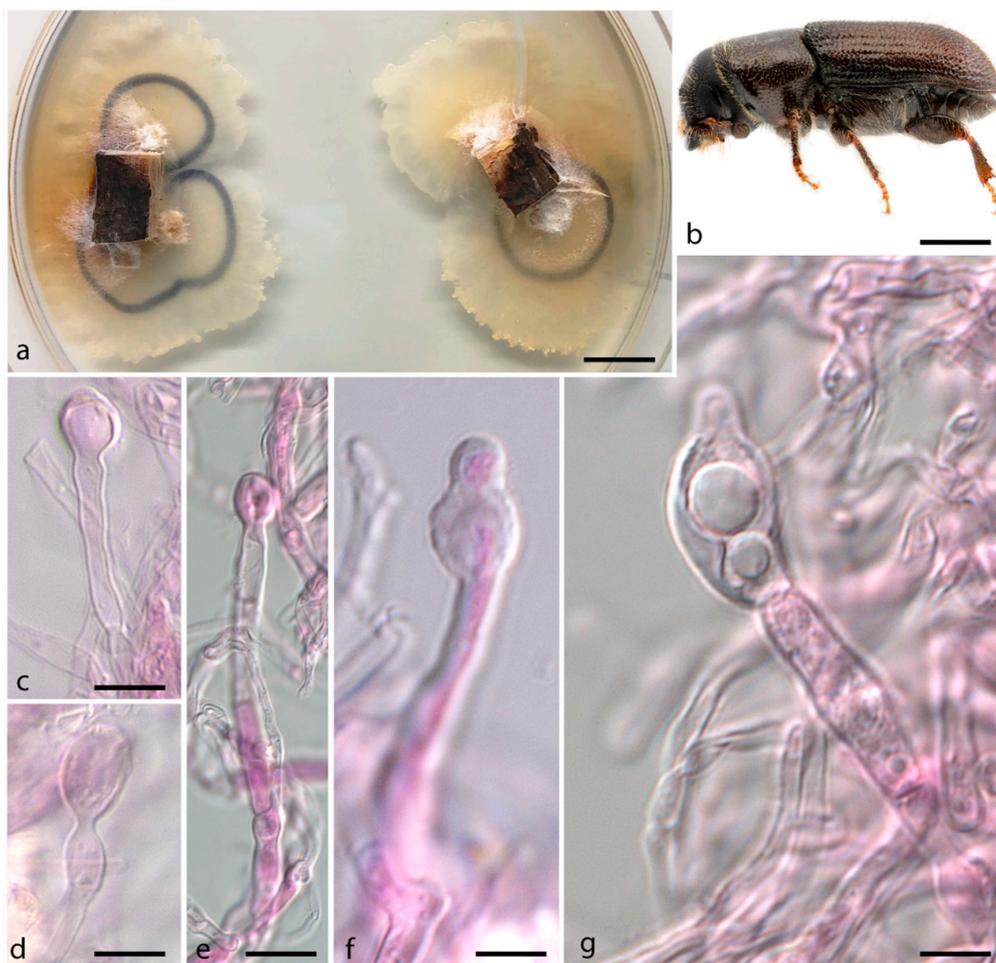

Figure 5. *Entomocorticium belizense*. (a) Culture aspect on PDA plate; (b) *Dendroctonus frontalis*; (c–f) Early stages of aleurioconidia; (g) Fully developed aleurioconidia. Scale bars: (a) = 1 cm; (b) = 0.5 cm; (c–g) = 5 μm .

Etymology. Named after the place of origin where it was collected, Belize.

Typus. BELIZE, Mountain Pine Ridge, from *Dendroctonus frontalis* mycangium, 21 January 2019, J. Skelton, Y. Li & J. Hulcr (holotype FLAS-F-68309 (dried culture), ex-type CBS 148420 (live culture)).

Diagnosis. The fungus associated within *Dendroctonus frontalis* mycangium, inhabiting *Pinus caribaea*, exhibits characteristic papillate aleurioconidia.

Sexual morph not observed. *Asexual morph* composed of simple or sparsely branched hyphae that are 1.5–4 µm wide and irregularly septate, clamp connections not observed. *Hyphae* cylindrical and uniform, sparsely forming thin-walled chlamydospores av. 12 × 5 µm. *Aleurioconidia* is produced at the tips of some hyphae, thick-walled, spherical to ovoid, commonly papillate, 6.5–9 × 8–17 µm. *Cultures* irregular, light cream to tan, center cottony with scarce hyphae and adpressed edges.

Vector. *Dendroctonus frontalis* (Coleoptera, Curculionidae). Voucher UFFE:30866, GenBank accession number: OL631193.

Host. *Pinus caribaea* (Pinales, Pinaceae).

Distribution. Only recorded from Belize.

Additional specimens examined: BELIZE, Mountain Pine Ridge, from *Dendroctonus frontalis* (Voucher UFFE:30867) mycangium, 21 January 2019, J. Skelton, Y. Li & J. Hulcr (18051).

Entomocorticium macrovesiculatum Araújo, Li, Six & Hulcr, sp. nov.—MycoBank MB 839837; Figure 6.

Etymology. The name refers to the large vesicles commonly seen in this species.

Typus. USA, McCloud-CA, from *Dendroctonus brevicomis* mycangium, July 2014, D. Six & R. Bracewell (holotype FLAS-F-68310 (dried culture), ex-type CBS 148421 (live culture)).

Diagnosis. The fungus associated within *Dendroctonus brevicomis* mycangium, inhabiting *Pinus ponderosa*, exhibiting abundant large vesicles.

Sexual morph not observed. *Asexual morph* is composed of branched hyphae that are 2–6 µm wide and regularly septate, clamp connections present but rare. *Hyphae* cylindrical, often swollen, moniloid, sparsely forming abundant thin-walled vesicles 13 × 37 µm, commonly bursting when mounted for light microscopy. *Aleurioconidia* terminal or intercalary within hyphae, apparently produced by the enlargement of single cells, capitate to ovoid, abundant, 5.5–11 × 7–15 µm. *Cultures* irregular, white to light cream to tan, cottony center with lacunose and viscous margins.

Vector. *Dendroctonus brevicomis* (Coleoptera, Curculionidae)

Host. *Pinus ponderosa* (Pinales, Pinaceae)

Distribution. Recorded from several sites across the Western USA: Chiloquim (OR), Greenough (MT), McCloud (CA), Missoula (MT), Placerville (CA), Ruisoso (NM) and San Bernardino Mountains (CA).

Additional specimens examined: USA, Missoula-MT, from *Dendroctonus brevicomis* mycangium, 17 January 2019, D. Six & R. Bracewell (MI17); USA, Placerville-CA, from *Dendroctonus brevicomis* mycangium, 20 February 2019, D. Six & R. Bracewell (PL6). USA, Ruisoso-NM, from *Dendroctonus brevicomis* mycangium, 10 January 2019, D. Six & R. Bracewell (RO10).

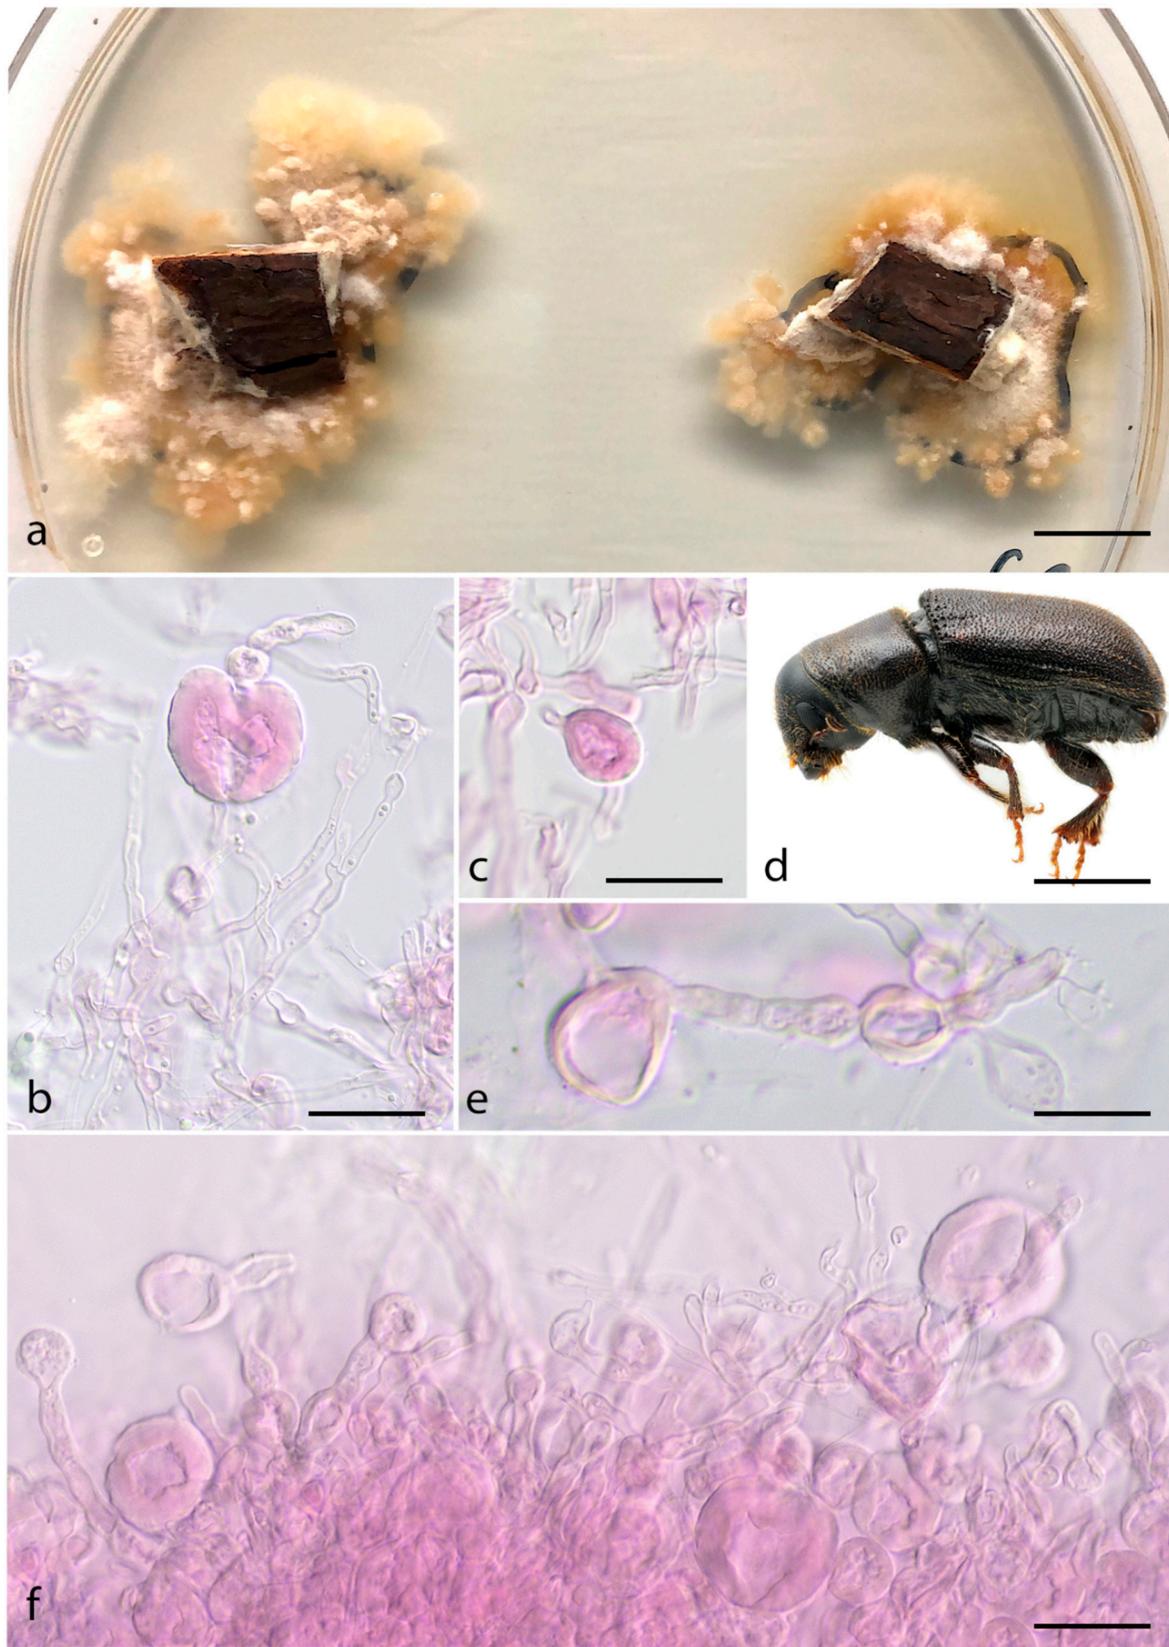

Figure 6. *Entomocorticium macrovesiculatum*. (a) Culture aspect, including two pieces of pine wood. Black line on the underside of the Petri dish indicates culture diameter on 22 December 2020, photo taken on 21 January 2021; (b,c) Chlamydospores; (d) *Dendroctonus brevicomis*, the vector; (e,f) Vegetative hyphae and chlamydospore-like/vesicles. Scale bars: (a) = 1 cm; (b) = 30 μ m; (c) = 20 μ m; (d) = 2 mm; (e) = 15 μ m; (f) = 30 μ m.

4. Discussion

In order to understand the evolution of symbiotic relationships, it is important to consider what factors have been involved in the acquisition of new hosts and vectors [39]. Host shifts by microbial symbionts are often associated with species diversification driven by the exploitation of new adaptive zones [40]. In the case of *Entomocorticium* and bark beetles, our results indicate a considerable diversity of fungal lineages within *Entomocorticium* with each species consistently associated with a particular taxon of bark beetles and their host pines.

Our phylogenetic results agree with the previously published phylogeny of *Entomocorticium* [15,16]. However, our study aimed to be more inclusive and provide further clarification regarding the evolutionary pathways that might have facilitated the origin of the genus *Entomocorticium* and promoted its further speciation. We propose a hypothesis of an evolutionary transition from a strictly wood-decaying, wind-dispersed fungal lineage (*Peniophora*) to a beetle-associated lineage engaged in highly selective vertical transmission through mycangia (*Entomocorticium*). We also provide new hypotheses on how beetle species involved in these symbiotic relationships likely played a crucial role in promoting diversity within this fungal group.

Our findings support *Entomocorticium* as a monophyletic fungal lineage that exhibits common morphological, molecular and ecological traits. Therefore, we are convinced that *Entomocorticium* should be treated as a separate genus from *Peniophora*, although that renders *Peniophora* a polyphyletic group. We hope that this study encourages further efforts to elucidate the relationships within *Peniophora*, which would ultimately result in a new taxonomic arrangement for the genus.

4.1. How Did Such Relationships Arise?

Our results indicate that most species within *Peniophora*, the genus from which *Entomocorticium* is derived, are broadly associated with angiosperms with at least five transitions to gymnosperms, particularly *Pinus* (Figure 1). Following one of these transitions (Figure 1 node A), the ancestor of *Entomocorticium* (related to *Peniophora pithya*) encountered bark beetles and transitioned to dissemination via beetle vectors. Given that *Peniophora* is a group of wood-rotting fungi that colonize and degrade dead wood, initial encounters between a member(s) of this group and bark beetles likely occurred in recently killed or moribund tree tissues. While *Entomocorticium* is likely undersampled in our analysis, our results indicate that twig beetles that exploit moribund phloem on shaded-out pine twigs (e.g., *Pityoborus*) were among the earliest vectors of these fungi (Figure 2).

The subsequent switches to new beetle vectors were likely facilitated by co-colonization of pine phloem by multiple species of bark beetles, resulting in exposure of the fungus to a diverse vector pool. Co-colonization of trees, i.e., niche overlap, is common in bark beetles and can result in exposure to a diverse pool of potential symbionts [41]. Shifts to new hosts may have driven both symbiont and beetle diversification in at least some cases by allowing the exploitation of new adaptive zones. Host-shift events driven by niche overlap are relatively common in fungi, especially within Hypocreales [39,42–45]. In the case of *Entomocorticium* and bark beetles, our results indicate a considerable diversity of lineages of these fungi, with each species consistently associated with a particular taxon of scolytine beetles in *Pinus*.

4.2. Distinct Associations across Bark Beetles and *Entomocorticium*

Not all symbioses between *Entomocorticium* and bark beetles are the same. There is a range of dependencies varying from loose and facultative (e.g., *D. ponderosae*) to obligate (e.g., *D. frontalis* and *D. brevicomis*) [46]. Likewise, the effects of the fungi on beetle fitness are not clear. For example, several species of *Entomocorticium* have been isolated from the pupal chambers of *D. ponderosae* and these have been suggested to be nutritional mutualists [15,16]. However, these fungal species have sporadic distributions with *D. ponderosae* [47,48] and have never been isolated from their mycangia [8,49], despite

numerous isolations from beetles collected in many locations. Additionally, these fungi have been only rarely isolated from the beetle's exoskeleton, suggesting the beetle may be an inefficient vector and the beneficial aspects of this symbiosis to the beetle, if any, is unreliable.

In contrast, *D. frontalis* and *D. brevicomis* are obligately associated with *Entomocorticium* species and these fungi provide crucial nutrients for the development of beetle larvae. The association of *D. brevicomis* with *Entomocorticium* is ancient and highly coevolved with the fungi co-speciating along with the host beetle in response to a period of isolation during glaciation [49]. Vertical transmission via highly selective mycangia enforces fidelity and reduces the potential for invasion by new lineages [46,50–55].

Regarding *Pityoborus comatus* and *Ips avulsus*, both species have been studied much less than *Dendroctonus*, but observational evidence of larval development suggests that they are completely mycophagous, at least in the larval stage. Some *Ips* species appear to be dependent on *Ophiostoma* species for nutrition [53] and this may also be the case for those that associate with *Entomocorticium*. However, most aspects of this association have not been investigated, especially regarding mycangia or other structures that facilitate fungal dissemination and little is known about specificity and nutritional effects.

4.3. Distinct Functional Traits in Basidiomycota and Ascomycota Associated with Bark Beetles

The association of *Entomocorticium* (Basidiomycota) with conifer-colonizing bark beetles is clearly limited compared to conifer-colonizing bark beetles occurring with Ophiostomatales (Ascomycota), which are ubiquitous worldwide [15]. For many bark beetles, Ophiostomatales fungal symbionts are facultative or obligate nutritional mutualists. The necrotrophic nature of many of these fungi allows them to survive and grow in a dying tree host during the early colonization phase of a tree and then to exploit dead tree tissues over the longer period of larval and fungal mycelial development [5]. Ophiostomatales do not degrade cellulose and lignin, which limits them to foraging for amino acids and simple carbohydrates [53].

On the other hand, the Basidiomycota symbiont species, such as those in the genera *Entomocorticium* and *Peniophora*, can actively decay the structural components of wood. Both genera are saprobic and do not invade living tissues, as demonstrated for the *Entomocorticium* species associated with *D. brevicomis* [53]. While they also consume amino acids and simple carbohydrates for energy and growth, they use these resources to support the degradation of cellulose and lignin, resulting in greater access to resources within the tree. These different qualities between the Ascomycota and Basidiomycota associates of bark beetles are not trivial and are critical to understanding the development and maintenance of such novel symbioses within bark beetles as a whole. Differences in growth within trees and the ability to access and acquire nutrients indicate different pathways to exploit wood as a niche and potentially to reduce niche overlap and competition [53].

4.4. Domestication of *Entomocorticium* by Beetles Facilitated the Loss of Morphological Traits

The transition from free-living (*Peniophora*) to beetle-associated (*Entomocorticium*) coincided with a transition to moribund phloem: a resource that presents benefits, as well as costs. Tree parts, such as moribund phloem are relatively free of competition and are more nutritious than dead wood or woody debris. However, moribund phloem is still alive and chemically defended and is also spatially patchy and intermittently available. Therefore, exploitation of such a resource is greatly facilitated by association with an agile insect vector. The optimal resource for the vector and the fungus are hence similar.

The overall loss of morphological complexity from *Peniophora* to *Entomocorticium* species is consistent with the loss of morphological features in other beetle-associated fungi [54]. Likewise, a reduction in sexual reproduction is consistent with predictions for microbes involved in mutualisms [51–53]. *Peniophora* are corticoid fungi that reproduce sexually and exhibit a broad diversity of basidiome morphologies (e.g., resupinate, effused, membranaceous, ceraceous, etc.), colors (e.g., reddish, orange, pink, violaceous, greyish,

yellow, lilac, etc.) and colonize wood of a broad variety of plant hosts [56,57]. In contrast, *Entomocorticium* are restricted to beetle-colonized *Pinus* and only form simple whitish mycelial mats, often supporting the production of large numbers of asexual spores (chlamydospores, aleurioconidia) and with sexual spores (basidiospores) formed only rarely or not at all [14–16]. Basidia, when they do form, have been described as lacking Buller’s drops reflecting their production inside the tree with no potential for wind dispersal. However, as with other putative asexual mutualists, evidence of rare recombination events can be found, potentially maintained to reduce the effects of Muller’s ratchet predicted for fully asexual species [58,59].

Bark beetles are tremendously important evolutionarily, ecologically, and economically, and their complex relationships with trees and fungi are beginning to be better understood [60,61]. The descriptions of new species we provide as well as their relationships are noteworthy. They expand upon recent descriptions from Harrington et al. [15], indicating greater complexity and diversity of fungal associates of *Dendroctonus* and other bark beetle species. This work also furthers understanding of the players in this group of model organisms for the study of symbiosis.

5. Conclusions

The genus *Entomocorticium* provides an interesting insight into the origins of insect microbial mutualisms. This lineage of Basidiomycota has arisen quite successfully from a wood-decaying ancestor (*Peniophora*) within a matrix of pre-existing symbioses between several lineages of Ascomycota fungi and their beetle vectors [5]. Targeted sampling for *Entomocorticium* across a variety of bark beetles with various tree colonization strategies, careful investigation of fungal vectoring capacity and specialized structures of beetles, and studies on the effects of the fungi on beetle fitness via nutrient provisioning should be a focus of future investigations into beetle-fungus symbioses. This is particularly true for *Entomocorticium* associated with *P. comatus*, a beetle which has not yet been found to associate with fungi in Ophiostomatales (Ascomycota), and also with *D. ponderosae*, a beetle which has not yet been shown to harbor *Entomocorticium* symbionts within the mycangia, only from its galleries. Genetic and morphological descriptions of the fungi can provide additional information on symbiosis type and strength, as well as provide a better understanding of the functional morphology of these fungal lineages and how they evolved. Furthermore, the diversity of fungi with bark beetles in *Pinus* in Mexico and Central America, which are almost completely unsampled, should be specially targeted. These regions exhibit amazing diversity of pines and bark beetles, and most likely fungal symbionts as well. For example, Mexico alone has 43 species of *Pinus* with a myriad of unknown beetle-fungus associations [62] and these diverse pine forests most likely harbor the largest reservoirs of these intriguing, fascinating and ecologically important fungi.
