Abstract: The International Roughness Index (IRI) has been accepted globally as an essential indicator for assessing pavement condition. The Laos Road Management System (RMS) utilizes a default Highway Development and Management (HDM-4) IRI prediction model. However, developed IRI values have shown the need to calibrate the IRI prediction model. Data records are not fully available for Laos yet, making it difficult to calibrate IRI for the local conditions. This paper aims to develop an IRI prediction model for the National Road Network (NRN) based on the available Laos RMS database. The Multiple Linear Regression (MLR) analysis technique was applied to develop two new IRI prediction models for Double Bituminous Surface Treatment (DBST) and Asphalt Concrete (AC) pavement sections. The final database consisted of 83 sections with 269 observations over a 1850 km length of DBST NRN and 29 sections with 122 observations over a 718 km length of AC NRN. The proposed models predict IRI as a function of pavement age and Cumulative Equivalent Single-Axle Load (CESAL). The model's parameter analysis confirmed their significance, and R^2 values were 0.89 and 0.84 for DBST and AC models, respectively. It can be concluded that the developed models can serve as a useful tool for engineers maintaining paved NRN.

Keywords: International Roughness Index (IRI); Laos Road Management System (RMS); Cumulative Equivalent Single-Axle Load (CESAL)

1. Introduction

As a landlocked country [1], the Lao People's Democratic Republic's (Lao PDR) connectedness with adjoining countries is of pivotal significance [2]. As the country has no harbor and has only 3.5 km of the railway link at the Thai border, the road network is an essential means of transportation to link Laos with its neighbors and within the country [3]. The transport sector is dominated by the road subsector, sharing 98% of the entire passenger-kilometers traveled and 86% of freight moved in the homeland [4].

The Laos road network is split into six classes: (i) National Roads (NRs) link the national capital to other provincial capitals and commercial centers and reach the global borders; (ii) Provincial Roads (PRs) link provincial capitals to district centers, river ports, tourist and important historic sites of the province; (iii) District Roads (DRs) link district commercial centers to rural areas; (iv) Urban Roads (URs), which are internal to cities and towns; (v) Rural Roads (RRs) link rural areas and utilities serving the rural houses; and (vi) Special Roads (SRs) serve definite purposes, such as connecting to sightseeing areas [5,6].

Significant expansion in the Lao PDR's road network has occurred over the last three decades [3]. The road network length has increased from 14,000 km in 1990 to 60,560 km in 2018. As shown in Table 1 [7], the highest share of the total length of the network was RR (43.23%), followed by PR (14.02%) and NR (12.45%), and the remaining 30.30% were DR, UR, and SR.

Table 1. Summary of Laos road network statistics from 2018.

Type of Road	Concrete	Asphalt	DBST	Gravel	Earth	Total	Percent
National Roads (km)	85.73	995.23	5426.01	794.95	238.05	7539.96	12.45%
Provincial Roads (km)	81.73	64.70	1770.69	5614.85	959.77	8491.74	14.02%
District Roads (km)	67.78	0.00	586.20	4244.73	2289.38	7188.09	11.87%
Urban Roads (km)	255.42	127.67	1219.02	1325.52	706.86	3634.50	6.00%
Rural Roads (km)	29.61	4.00	559.31	10,007.72	15,577.05	26,177.69	43.23%
Special Roads (km)	31.74	11.53	352.37	1198.02	5933.89	7527.56	12.43%
Total Length (km)	552.02	1203.13	9913.60	23,185.79	25,705.00	60,559.54	
Percent	0.91%	1.99%	16.37%	38.29%	42.45%		

DBST—Double Bituminous Surface Treatment.

Paved roads are grouped into three families: Cement Concrete (CC), Asphalt Concrete (AC), and Double Bituminous Surface Treatment (DBST). While the road network in Laos is extensive, only 19.27% of the roads' total length is paved (using CC, AC, and DBST), 38.29% is gravel, and the residual 42.45% is of earth construction.

The NRs cover approximately 7540 km of the road network, the majority of which (86.30%) have a paved surface, whereas RRs, URs, DRs, PRs, and SRs are generally earth or gravel roads and are vulnerable to pouring rain and floods. Most NRs' paved sections are DBST (71.96%), while AC and CC comprise only 13.20% and 1.14% of them, respectively.

Pavement condition can be assessed depending on four aspects: structural capacity, surface distress, skid resistance, and ride quality [8]. Ride quality is commonly connected with users' comfort level regarding the traveled roadway, which is influenced by pavement roughness [9]. Pavement roughness illustrates unevenness in the roadways' surface, which is calculated in terms of the International Roughness Index (IRI) [10].

The IRI is so-called because it was an output of the International Road Roughness Experiment (IRRE), executed by researchers from the United States, England, Brazil, Belgium, and France to identify such an index [11]. In 1982 [12], the IRRE was launched by the World Bank to create correlation and a calibration standard for roughness measurements [13]. The IRRE involved the controlled measurement of road roughness for several roads under various conditions and by a variety of methods and equipment [11].

The prime principles in designing the IRI were being transportable, relevant, and settled over time while also being measured easily [11,14]. It had to be measurable with a broad range of equipment to secure transportability, including response-type systems. It had to be described as a mathematical conversion of a measured profile to be steady over time [15].

The IRI is defined as "the accumulated suspension vertical motion divided by the distance traveled as obtained from a mathematical model of a simulated quarter-car traversing a measured profile at 80 km/h" [15,16]. IRI values are expressed as the slope units (m/km, in/mi, etc.), with a high value indicating extremely rough road [17]. The lower the IRI value, the flatter the paved surface [18].

The IRI epitomizes the roughness condition that affects vehicle response and is of utmost suitability for evaluating overall vehicle operating cost, overall ride quality, dynamic wheel loads [14], and general surface condition [19].

The IRI data are usually surveyed by the Laos Public Works and Transport Institute (PTI) at different frequencies, depending on the available funds [20]. The NRN is monitored at frequent intervals, often 2–3-year intervals. Paved sections are categorized into six groups, based on predetermined criteria for roughness adequacy, as shown in Table 2.

Table 2. The Roughness Scale of the International Roughness Index (IRI).

Pavement Condition	Excellent	Good	Fair	Poor	Bad	Failed
IRI (m/km)	<3	3 to 4	4 to 5	5 to 6	6 to 8	>8

A well-constructed pavement, newly laid, also has an initial IRI value (IRI just after construction), and it continues to rise over time where the pavement deteriorates [21]. Pavement deterioration can be attributed to different factors such as traffic loads, pavement age, material properties, environment condition, subgrade properties, and pavement strength, which influence the pavement's mechanical characteristics [8]. Many highway agencies worldwide deal with the initial IRI value as a quality assertion norm and the terminal IRI as an index of required pavement maintenance and rehabilitation activities [22].

An IRI condition survey of the NRN was conducted in 2016, which pointed out that 48% of the paved sections were in excellent, good, or fair condition, with nearly 30% in bad or poor condition and approximately 22% categorized as having failed [20]. A Vehicle Intelligent Monitoring System (VIMS) was introduced as the IRI survey equipment. It was found to be relatively accurate and less expensive than other systems, which usually require a specially equipped vehicle to measure IRI. VIMS was introduced under the technical support of Nagasaki University [23].

In 2004, as a result of limited budget and growing challenges in pavement maintenance and rehabilitation strategies, the Road Management System (RMS) was developed for NRs based on Highway Development and Management (HDM-4) models with aid from the World Bank [24]. RMS comprises several analysis modules, such as a Road Database (RDB), Bridge Management System (BMS), Pavement Management System (PMS), and Traffic Monitoring System (TMS).

RMS is used to formulate road's short- and medium-term maintenance strategies, select priority projects, and choose optimum maintenance activity plans. In 2008, RMS was incorporated with the Provincial and Rural Roads Management System (PRoMMS), so it became achievable to develop maintenance plans for rural and provincial roads too [24].

The RMS/PRoMMS database has been improved and updated throughout the period (2012–2016) by the JICA expert team as part of the Project "Improvement of Road Management Capability in Lao PDR" [23]. The pavement deterioration models are essential for PMS and are utilized to define various functions [8], as follows:

- Rate of pavement degradation at both the project and network level,
- Evaluation of pavement assets (residual service life), and
- Road user costs.

Laos PMS utilizes a default HDM-4 pavement deterioration models to predict IRI. However, developed IRI values have illustrated the need to calibrate the IRI forecasting model based on Laos' local conditions or create a new IRI model.

Over the years, research agencies and individual researchers have developed various IRI prediction models [21,22,25–35]. Some of these models were developed utilizing the Long-Term Pavement Performance (LTPP) database, whereas others were derived depending on direct field measurements or the domestic agency database. The results from some of these studies are summed up in Table 3.

From the above literature review, it is apparent that the variables such as pavement age, the structural strength of pavement, traffic loads, pavement defects, and environmental conditions enormously affect the progression of roughness (IRI value). The calibration and application of the Mechanistic–Empirical Pavement Design Guide (MEPDG) or HDM-4 models by highway agencies demand detailed and precise distress data [36]. Such data records are not quite available for Laos yet, making it difficult to calibrate the HDM-4 IRI prediction model for local conditions.

So, the domestic roughness deterioration models for various pavement categories have to be developed covering the influence of Laos' local conditions, which would have direct implementation without any calibration factors based on accessible data in the Laos RMS. The developed models' primary objective is to evaluate and predict the Laos NRN's condition to assist the responsible authorities in making consistent and cost-effective decisions related to pavement sections' maintenance and rehabilitation.

Table 3. Synopsis of Literature IRI Prediction Models.

First Author, Year	Pavement Type	Source of Data	Prediction Method	Independent Variables ¹	Goodness of Fit
Von Quintus, 2001 [31]	Conventional HMA with thick granular base	LTPP database, GPS and SPS	Stepwise linear regression	IRI ₀ , TC, COVRU, FC, BC, LCSNWP, AGE, RSD, Rm, P ₂₀₀ , P _{0.02} , PI, FI	R ² = 0.62, RMSE = 0.387 m/km, N = 353

2. Methodology

The research methodology followed in this study began by reviewing the pertinent literature. The required data were then collected from different resources, mainly from the Laos RMS database. After that, the data processing was accomplished. Finally, the MLR analysis technique in Statistical Package for the Social Sciences (SPSS) was applied to evolve a regression model to correlate IRI with the study's variables. Fundamental statistical analyses were conducted to verify and explain the proposed models' sensitivity. The research methodology is summed up in Figure 1.

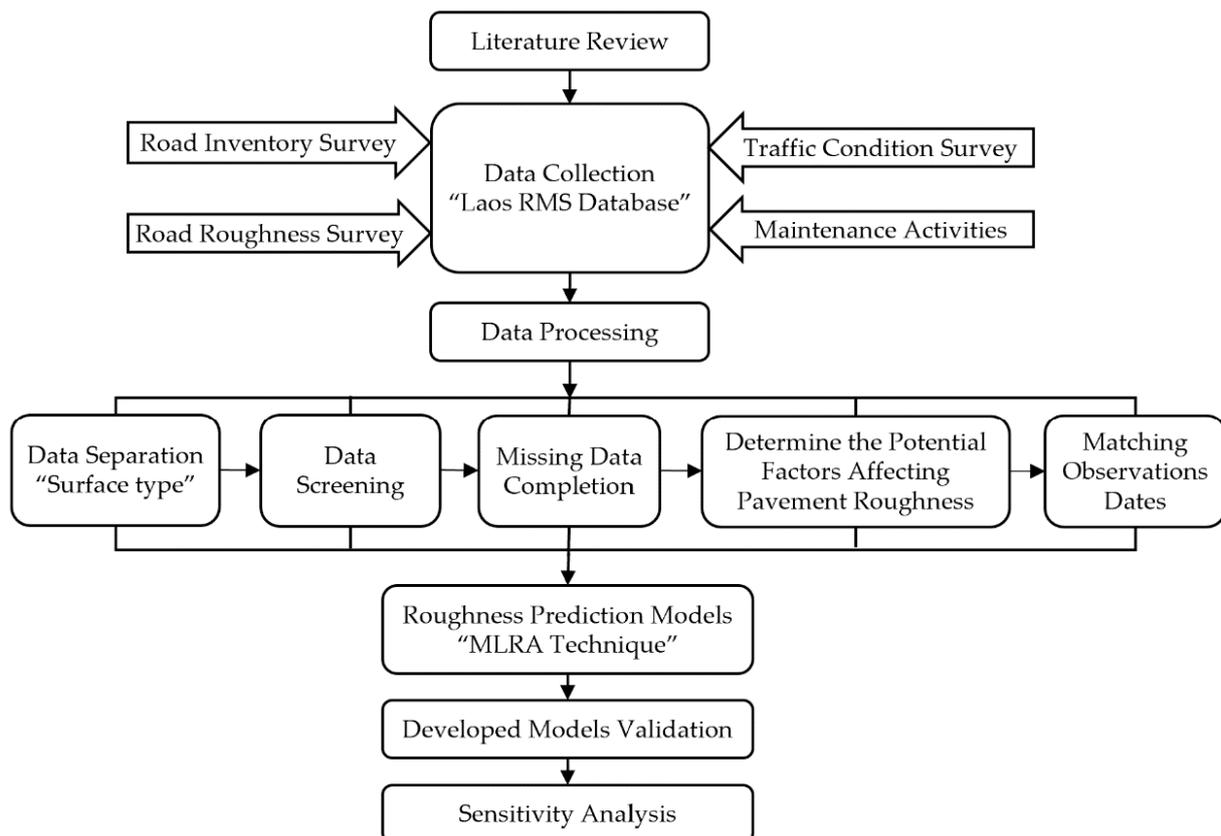

Figure 1. Flow chart of the research methodology.

2.1. Data Collection

A broad number of precise and valid data are necessary to develop a regression model of the IRI and the variable's effect on it. This study was planned to cover 14 years, starting from 2001 to 2015, to track development trends of pavement roughness condition over a total length of 7540 km of the NRN.

Every road in the NRN is separated into homogeneous sections. A homogeneous section can be defined as "a section of pavement that has uniform characteristics along its length, for instance; structural design, pavement materials, subgrade condition, number of lanes, construction (by the same contract), age since opening for service, the proportion of truck traffic, and maintenance actions applied" [37]. Then, each pavement section is divided into 100 m sample units. For every homogeneous section, the following data are obtainable from the Laos RMS database:

- Road Inventory Survey (RIS): road and section number, section length and width, surface type, no. of lanes, shoulder type and width, kilometeric stations, road category, and survey date.
- Road Roughness Survey (ROS): 100 m interval IRI values over each section's entire length. The IRI data were measured at an approximate speed of 80 km/h for the

right (outer) wheel track without any specific criteria for the distance from the road's pavement edge.

- Traffic Condition Survey (TCS): annual average daily traffic (AADT), traffic growth rates, classified traffic volume survey, and vehicle classification (See Table 4).
- Last maintenance activity type and date.

Table 4. Laos vehicle classifications.

Class Group	Description	Class Group	Description
Class 1	Bicycle	Class 8	Small bus (max 12 seats)
Class 2	Oxcart	Class 9	Medium bus (from 13 to 25 seats)
Class 3	Minitractor	Class 10	Heavy bus (more than 25 seats)
Class 4	Motorcycle	Class 11	Light truck (less than 4 tons)
Class 5	Tuk-tuk	Class 12	Medium truck (2 axles)
Class 6	Passenger car	Class 13	Heavy truck (3 axles or more)
Class 7	Pick-up	Class 14	Truck trailer

2.2. Data Separation

In this study, the pavement family approach is applied [38], in which pavement sections with identical surface properties are clustered into families. The pavement sections in the NRN are clustered into families as following; AC, DBST, and CC.

After the pavement families are specified and the sections clustered correspondingly, the data for homogeneous sections are gathered from the Laos RMS database. There are six observations for each section in the following years: 2001, 2004, 2008, 2013, 2014, and 2015. An identification code is applied to define each observation. It is an unparalleled collection of attributes as follows: road number, section number, and the IRI survey year (e.g., 13N_S_2008).

2.3. Data Screening

The assembled data were thoroughly checked for irregularities and missing data from collection or documentation. The data were also reviewed and cleaned for oddity and gross data errors. In this study, the total number of 1214 observations from 254 sections covered the paved NRN. The 100 m interval IRI values were averaged over each section's entire length.

A linear relation between IRI and pavement age for whole sections was investigated to examine the IRI data against possible irregularities. The sections that demonstrated the negative trend (lessening IRI value over time) and unexplainable fluctuations in condition were excluded from this study. The negative IRI trend was observed due to the implementation of some maintenance activities on the pavement section without registration in the RMS database. Accordingly, IRI values decreased, and a negative trend appeared with pavement age, contrary to expectations of increasing IRI values due to the positive effect of the traffic loads and not carrying out any maintenance activities according to the RMS database. Figure 2 shows examples of the negative trend and fluctuations of IRI along with pavement age.

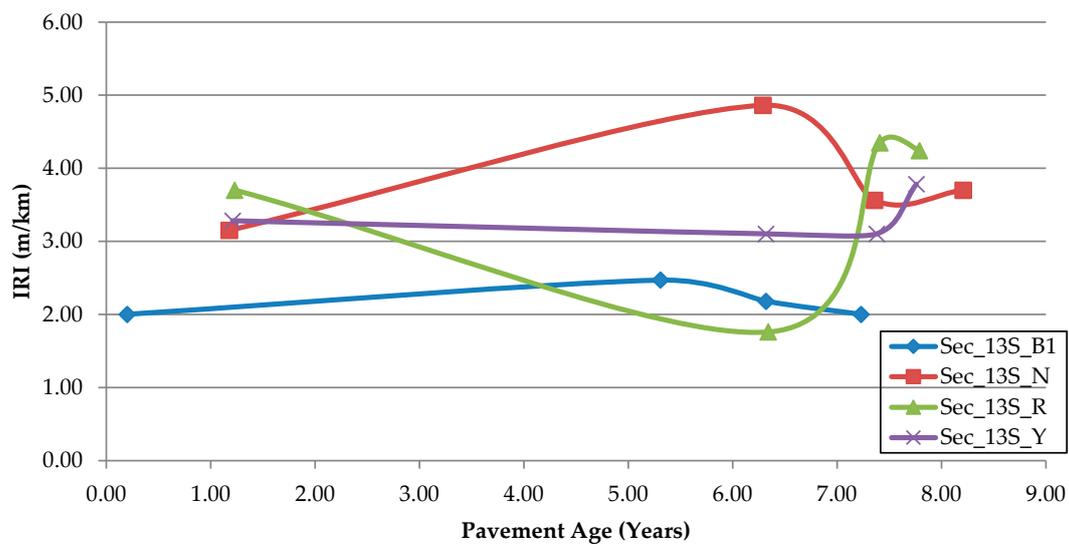

Figure 2. Examples of irregularities in IRI data along with pavement age.

Thus, the valid number of sections and observations was diminished, as presented in Table 5. The number of valid observations available for the CC surface type was inadequate for developing a reliable model. Therefore, the analysis was limited to DBST and AC surface types, utilizing the valid number of observations, including 269 observations from 83 sections covering a total length of 1849.26 km of DBST NRs and 122 observations from 29 sections covering a total length of 718.55 km of AC NRs.

Table 5. Summary of the number of sections and observations in each surface-type group.

Surface Type	Total No. of Sections	Total No. of Observations	Valid No. of Sections	Valid No. of Observations
DBST	214	997	83	269
AC	36	184	29	122
CC	4	33	2	6

2.4. Missing Data Completion

The Laos RMS database lacks the initial AADT measurements. To overcome this problem, a regression model for every section among measured AADT and corresponding pavement age (started from the traffic opening date) was developed based on the available observations for backcasting the initial AADT data. The statistics of the developed regression models of the studied sections are summarized in Table 6.

Table 6. Statistics of developed regression models for backcasting initial AADT.

Surface Type	No. of the Best Fitting Relationship Type				Avg. R ²
	Exponential	Linear	Logarithmic	Power	
DBST	44	27	8	4	0.94
AC	10	10	-	9	0.97

2.5. Determining the Potential Factors Affecting Pavement Roughness

This study considered the factors of pavement age and Cumulative Equivalent Single-Axle Loads (CESAL). Despite the significant influence of the initial IRI₀ value, pavement structural capacity, and subgrade soil properties on the progression of the unevenness [21,22,31,33–35], an assessment of the effect of those factors on IRI progression was not possible, since the Laos RMS database does not have any information regarding those variables. The same usually happens in many developing countries where pavement history data are not available, especially for the network level [39,40]. The data required

to calculate pavement age and CESAL factors were extracted mainly from the Laos RMS database. Below is a brief description of these factors and how they were calculated.

2.5.1. Pavement Age

The pavement age is the usual factor employed in roughness modeling [41]. The Laos RMS database provides a survey date for IRI inspection and last maintenance activity type and application date. The variable age is calculated for every observation by subtracting the IRI survey date from the last major rehabilitation (overlay) or reconstruction date (those actions that directly influence the IRI in terms of improving smoothness after their application). The pavement age is expressed in days.

2.5.2. Cumulative Equivalent Single-Axle Load (CESAL)

A load applied on pavement varies based on the wheel configuration, traffic volume, gross vehicle weight, and the number of lanes in each direction. The impact of uneven traffic loads is transformed to a standard axle (18 kips), referred to as the Equivalent Single-Axle Load (ESAL).

Data required for calculating CESAL were collected mainly from the Laos RMS database, and other data were collected from governmental reports and the Laos road design manual. The following steps explain how to calculate CESAL:

- **Axle load distribution:** The axle load distribution, wheel configuration, and maximum gross vehicle weight amongst commercial vehicles that use NRs were collected from the Ministry of Public Work and Transport (MPWT), Lao PDR (as shown in Figure 3). The legal axle load limits enforced in Lao PDR are as follows: 9.10 tons for single-axle 4-wheelers, 6.80 tons for single-axle 2-wheelers, 6.10 tons (per axle) for tandem-axle 4-wheelers, and 6.80 tons (per axle) for triple-axle 4-wheelers [6,42].
- **Equivalent Axle Load Factor:** The ratio of the destructive effect of a nonstandard axle load to a standard axle load is called the Equivalent Axle Load Factor (EALF) [44]. The number of repetitions under every single-, tandem-, or triple-axle load should be multiplied by its EALF to get the equivalent effect depending on an 80 kN single-axle load. Equation (1) is used to calculate the EALF for different axle loads applied in Laos commercial vehicles [6].

$$EALF = \left(\frac{\text{Axle load (kg)}}{8160} \right)^{4.5} \quad (1)$$

- **Truck Factor (TF):** TF can be counted for every vehicle by collecting all vehicle EALF values. Then, an average TF is calculated for each vehicle class (e.g., medium trucks, heavy trucks, and truck trailers) by collecting the ESAL of all vehicles in every class and dividing by the number of vehicles using Equation (2).

$$TF_i = \left(\sum_{j=1}^n EALF_j \right) / n \quad (2)$$

where: TF_i = Truck factor for the i th vehicle class, n = vehicle number in the i th vehicle class, $EALF_j$ = Equivalent Axle Load Factor for the j th vehicle.

- **Cumulative Equivalent Single-Axle Load:** The data and parameters obtained from the prior sections can now be utilized to calculate the CESAL using Equation (3) [45].

$$CESAL = 365 * DF * LF * \frac{[(1+r)^n - 1]}{r} \sum (AADT_0)_i (TF_i) \quad (3)$$

where: DF = Directional Factor is the ratio of ESAL allocation by direction. LF = Lane distribution Factor is the ratio of traffic volume allocation over lanes in one direction. $(AADT_0)_i$ = Initial annual average daily traffic for the i th vehicle category in both

directions. TF_i = Truck factor for the i th vehicle category. r = Traffic growth rate, found in the Laos RMS database. n = Design period.

 <p>Weight Limit/Load Requirements</p>	 <p>2 axles / 4 wheels Max. G.W. 8500 kgs.</p>	 <p>2 axles / 6 wheels Max. G.W. 12000 kgs.</p>	 <p>3 axles / 6 wheels Max. G.W. 15300 kgs.</p>	 <p>3 axles / 10 wheels Max. G.W. 21000 kgs.</p>	 <p>3 axles / 6 wheels Max. G.W. 10500 kgs.</p>
 <p>3 axles / 8 wheels Max. G.W. 14000 kgs.</p>	 <p>4 axles / 8 wheels Max. G.W. 18800 kgs.</p>	 <p>4 axles / 12 wheels Max. G.W. 25200 kgs.</p>	 <p>3 axles / 10 wheels Max. G.W. 21100 kgs.</p>	 <p>4 axles / 14 wheels Max. G.W. 30100 kgs.</p>	 <p>4 axles / 14 wheels Max. G.W. 28400 kgs.</p>
 <p>5 axles / 18 wheels Max. G.W. 37400 kgs.</p>	 <p>6 axles / 22 wheels Max. G.W. 41400 kgs.</p>	 <p>2 axles / 4 wheels Max. G.W. 13600 kgs.</p>	 <p>2 axles / 6 wheels Max. G.W. 15900 kgs.</p>	 <p>2 axles / 8 wheels Max. G.W. 18200 kgs.</p>	 <p>3 axles / 12 wheels Max. G.W. 25500 kgs.</p>

Figure 3. Axle and wheel configuration for commercial vehicles in Lao PDR [43].

2.6. Matching Observation Dates

It was noticed that both IRI measurements and traffic survey dates in Laos RMS were not necessarily surveyed simultaneously. The IRI survey date was taken as a reference date to solve this issue, where CESAL measurements for homogenous sections were calculated at its corresponding IRI survey date.

3. Result

3.1. Regression Model Development

Before the data could be analyzed, the significance of each variable calculated was first studied utilizing the Pearson correlation coefficient. Another issue that needed special attention was the problem of multicollinearity among variables. Multicollinearity emerges in the model when independent variables that are strongly correlated exist [46]. For instance, the moderate correlation between the age variable and the CESAL is 0.57 in AC data modeling.

The average Yearly Equivalent Single-Axle Loads (YESAL) ratio (average CESAL over pavement age) was used instead to overcome this problem [38]. As shown in Table 7, a good correlation exists between IRI and independent variables, while a low correlation exists between independent variables themselves to avoid multicollinearity.

Table 7. Pearson correlation coefficient matrixes.

Variable	DBST Model			Variable	AC Model		
	IRI	AGE	CESAL		IRI	AGE	YESAL
IRI	1	0.85	0.73	IRI	1	0.82	0.64
AGE	0.85	1	0.42	AGE	0.82	1	0.31
CESAL	0.73	0.42	1	YESAL	0.64	0.31	1

YESAL—Yearly Equivalent Single-Axle Loads.

The database was randomly sorted and split into two sets to eliminate any possible bias, referred to as the “in-sample” and “out-of-sample” data. The in-sample group composed most of the data, at around 80 percent, which was utilized to develop the regression models. The residual 20 percent of the data, referred to as the “out-of-sample” or “testing data”, was utilized to assess the regression equations’ prediction efficiency. The developed models would represent all sections’ mean behavior in a particular pavement family. The basic statistics of data utilized for the model’s development and validation are shown in Table 8.

Table 8. Basic statistics of data utilized for the model’s development and validation.

Variable Description	Notation	Unit	Range		Mean	Std. Deviation
			Min	Max		
DBST Model						
Roughness	IRI	m/km	2.20	8.91	5.09	1.44
Pavement age since the last overlay	Age	years	0.10	14.10	6.03	3.73
Cumulative Equivalent Single-Axle Load	CESAL	10 ⁴ axles/lane	0.02	99.26	13.28	16.55
AC Model						
Roughness	IRI	m/km	1.47	5.46	3.54	1.02
Pavement age since the last overlay	Age	years	0.09	13.08	5.95	3.44
The average Yearly Equivalent Single-Axle Load	YESAL	10 ⁴ axles/lane	0.03	20.53	4.42	3.34

IRI was chosen as the dependent variable in these models, and the counted pavement parameters—age, CESAL (DBST model), and YESAL (AC model)—were selected as the independent variables. After many modeling attempts, the most precise regression models were determined, as depicted in Table 9.

Table 9. Summary of regression statistics by pavement type.

Pavement Type	Model Equation	R ²	Std. Error of Estimate	No. of Observations
DBST	IRI = 3.006 + 0.259 age + 0.038 CESAL	0.892	0.483	215
AC	IRI = 1.782 + 0.203 age + 0.123 YESAL	0.847	0.395	98

The above models show that the IRI’s average initial values for DBST and AC pavement sections after overlay or reconstruction (when age and CESAL/YESAL are considered to be zero) are 3.006 and 1.782 m/km, respectively. Further, IRI has a direct relationship with both age and CESAL/YESAL, as they appear with positive coefficients. Also observed was the high values of the coefficient of determination (R²), indicating a good correlation between the dependent variable IRI and independent variables such as age and CESAL/YESAL. This agrees with the previous studies’ findings [22,32–34] that IRI is directly affected by pavement age and traffic loads.

The difference between the predicted and observed IRI values (residuals) are plotted against the predicted IRI values in Figure 4. The residuals vary mainly between −2 and

2 m/km and expand in a horizontal band around the zero line. No specific pattern is observed in the residuals' distribution, indicating a good fit for a linear model.

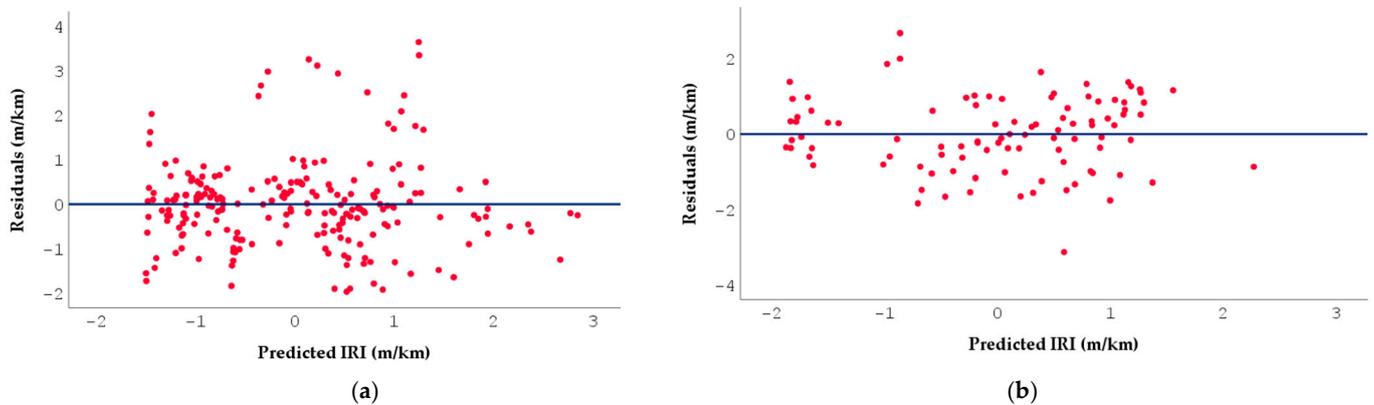

Figure 4. Graph of residuals versus predicted IRI for the (a) DBST model and (b) AC model.

3.2. Model Validation

A graph of the observed IRI values of the “out of sample” data and predicted IRI values from proposed models was outputted to assess the developed models' robustness, as illustrated in Figure 5. The alignment of sketched points along the line of equality points out the developed models' soundness.

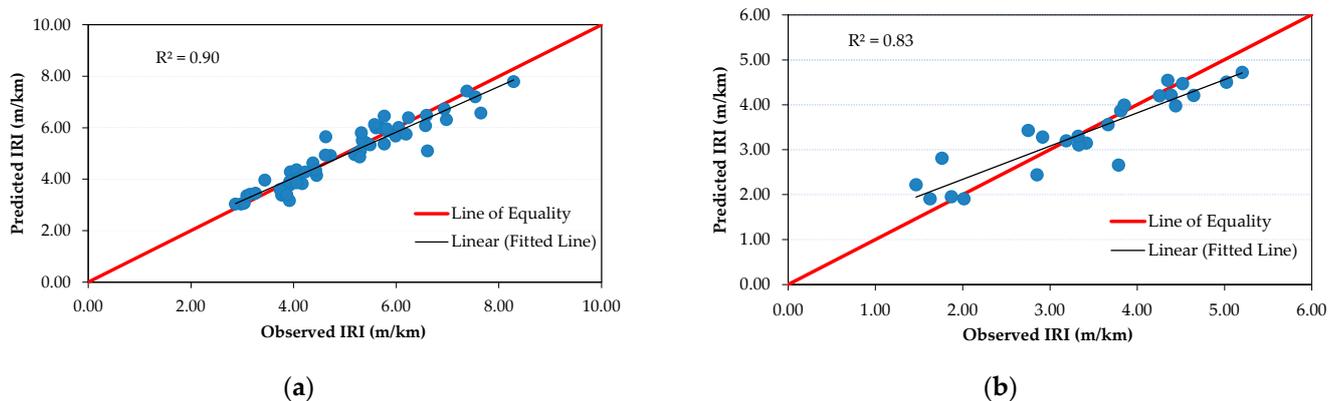

Figure 5. Observed IRI versus predicted IRI values for the (a) DBST model and (b) AC model.

3.3. Statistical Validity of the Developed Models

In order to verify the models' statistical validity and to audit the significance of the variables, an Analysis of Variance (ANOVA) was conducted on the regression outcomes. It was implemented with the null hypothesis that the IRI is not linked to pavement age and CESAL/YESAL. In contrast, the alternative hypothesis was that IRI is linked to the aforesaid independent variables. Furthermore, every independent variables' coefficient was assessed by another hypothesis test, where the coefficient was equal to zero in the null hypothesis and was not equal to zero in the alternative hypothesis.

Tables 10 and 11 illustrate the regression coefficients obtained from the ANOVA test and the hypothesis test. The null hypothesis in both tests is unacceptable as the p -value was less than 0.05 in both of them. Thus, all models' variables are agreeable and significant for predicting IRI value. Also, it was observed that the Variance Inflation Factor (VIF), as shown in Table 11, has a small value (less than 10) [47] for all independent variables, which eliminates the potential of multicollinearity among them.

Table 10. ANOVA results.

	df	Sum of Squares	Mean Square	F	p-Value
DBST Model					
Regression	2	406.912	203.456	872.091	3.6858×10^{-103}
Residual	212	49.459	0.233		
Total	214	456.370			
AC Model					
Regression	2	82.508	41.254	263.848	8.0861×10^{-39}
Residual	95	14.854	0.156		
Total	97	97.362			

Table 11. The performance prediction models' statistics.

Independent Variable	Coefficient	Std. Error	Student's t	p-Value	VIF
DBST Model					
Age	0.259	0.010	26.426	3.7348×10^{-71}	1.214
CESAL	0.038	0.002	18.265	1.5469×10^{-45}	1.214
AC Model					
Age	0.203	0.012	16.405	2.4503×10^{-29}	1.105
YESAL	0.123	0.012	10.230	2.6803×10^{-16}	1.105

VIF—Variance Inflation Factor.

3.4. Sensitivity Analysis of Roughness Models

To explain the IRI model's sensitivity to pavement age, a graph was made among random pavement age values, and the corresponding IRI values were gained from the proposed model considering the mean value (13.28) of CESAL for DBST sections and the mean value (4.42) of YESAL for AC sections. Figure 6 shows the line's steepness, indicating the models' sensitivity for slight variation in pavement age value. It can be noticed that the IRI value in the DBST model increases by 0.259 m/km and by 0.203 m/km in the AC model when the age value rises by one year.

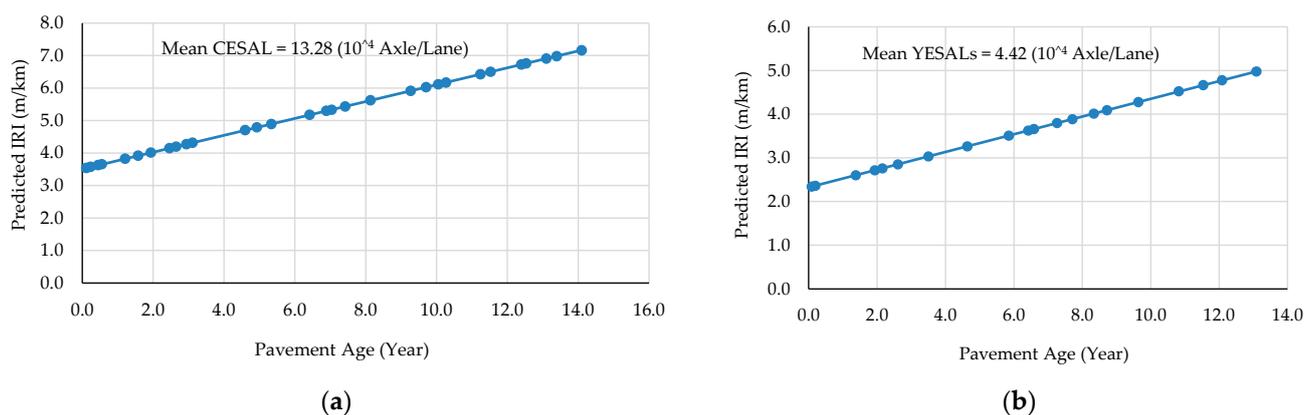

Figure 6. The relation among predicted IRI and pavement age for sensitivity analysis for the (a) DBST model and (b) AC model.

Also, to explain the IRI model's sensitivity to traffic loads, a graph was made of random CESAL/YESAL values and the corresponding IRI values gained from the proposed model considering the mean age values of 6.03 years for DBST and 5.95 years for AC sections. Figure 7 shows the line's steepness, indicating the models' sensitivity for slight variation in CESAL/YESAL value. It can be noticed that the IRI value rises by 0.03 and

0.123 m/km in DBST and AC models, respectively, when the CESAL/YESAL value rises by 10^4 axles/lane.

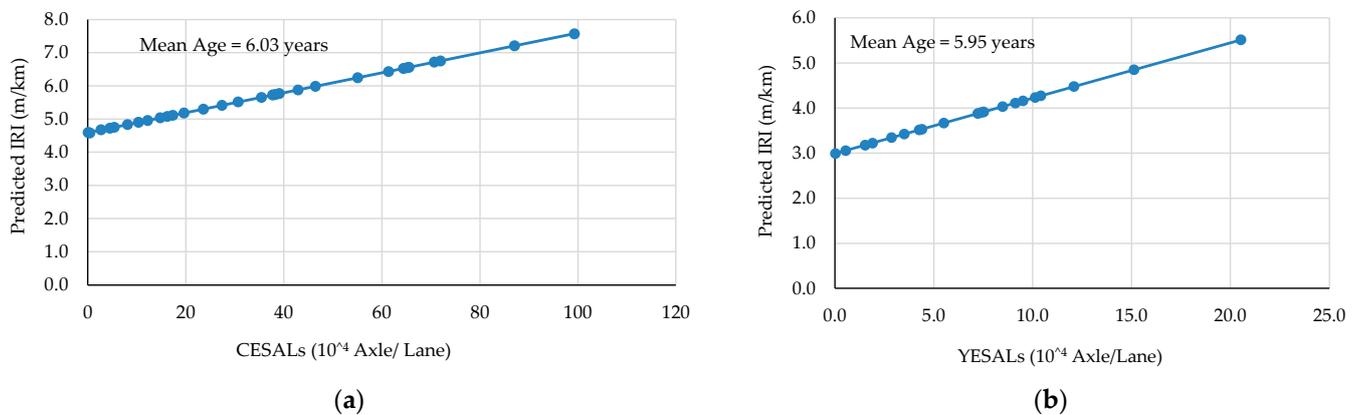

Figure 7. The relation among predicted IRI and traffic loads (CESAL/YESAL) for sensitivity analysis of the (a) DBST model and (b) AC model.

4. Discussion

The data available in the Laos RMS were utilized to develop two indigenous IRI prediction models for DBST and AC pavement sections. Regression analysis revealed that for DBST sections, age and CESAL are linearly correlated with IRI. Furthermore, the IRI for AC sections was found to depend on age and YESAL. The developed models can be incorporated into the Laos RMS to provide a better estimation of IRI values, which in turn will improve the evaluation and prediction of Laos NRs' pavement condition, thus assisting in making consistent and cost-effective maintenance decisions. The effect of pavement structural capacity as an independent variable on IRI progression will be further studied.

Author Contributions: Investigation, methodology, data curation, formal analysis, and writing—original draft preparation, M.G.; conceptualization, resources, validation, writing—review and editing, and supervision, T.N. All authors have read and agreed to the published version of the manuscript.

Funding: This research was funded by JICA, Road Asset Management Project, grant number (D1810488).

Informed Consent Statement: Not applicable.

Data Availability Statement: The data presented in this study are available on request from the corresponding author. The data are not publicly available due to privacy restrictions.

Acknowledgments: The authors would like to thank the Laos Public Works and Transport Institute (PTI), Ministry of Public Work and Transport, for granting permission to use the Laos RMS database for developing the pavement roughness models.

Conflicts of Interest: The authors declare no conflict of interest.

Appendix A

Table A1 illustrates the abbreviations and definitions of variables that have been used in the IRI literature review models.

Table A1. The abbreviation and definition of variables used in the IRI literature review models.

Abbreviation Symbols	Variable Name	Abbreviation Symbols	Variable Name
IRI ₀	Initial IRI	TLF	Time Lapse Factor
AGE	Pavement age since last overlay reconstruction or new construction	RL	Ravelling as percent of total lane area
AGE ₀	Initial age	RUT	Rutting
ΔAGE ₀	Difference in AGE ₀	SDRU	Standard Deviation of Rut Depth
AADT	Average Annual Daily Traffic	COVRU	Rut Depth Coefficient of Variation
ESAL	Equivalent Single-Axle Load	TC	Transverse Cracking
CESAL ₀	Initial Cumulative ESAL	MC	Miscellaneous Cracking
ΔCESAL ₀	Difference in CESAL ₀	FC	Fatigue Cracking
CVPD	No. of Commercial Vehicles per day	BC	Block Cracking
MSN	Modified Structural Number	PI	Plasticity Index
SNPK _b	Adjusted Structural Number due to Cracking	ΔRDS	Incremental change in standard deviation of rut depth
BTH	Base Layer Thickness	P	Patches as percent of total lane area
HSOLD	Total thickness of previous underlying surfacing layers	LCSNWP	Sealed Non-Wheel Path Longitudinal Cracking (WPLC)
HSNEW	Thickness of most recent surfacing	LCNWP	Non-WPLC
ACTH	Asphalt Concrete Overlay Thickness	LCS	Sealed WPLC
Rm	Average Annual Rainfall	ACX _a	Area of Indexed Cracking
RSD	Standard Deviation in Monthly Rainfall	PACK	Area of Previous Indexed Cracking in the old surfacing
FI	Freezing Index	ΔACRA	Incremental change in area of total cracking
M	Environmental Coefficient	NPT _a	Number of Potholes per km
P ₂₀₀	Percent Passing No.200 sieve	ΔNPT	Incremental change in NPT _a
P _{0.02}	Percent Passing 0.02 sieve	PH	Potholes as percent of total lane area
FM	Freedom of Maneuvering Index
