Message from the Guest Editor

Dear Colleagues,

Giant cell tumor (GCT) of the bone is a locally aggressive and rarely metastasizing primary bone tumor.

The controversial treatment is decided by the balance between an adequate surgical margin and sufficient adjacent joint function.

Curettage with a high-speed burr and local adjuvants is the most indicated treatment for active lesions, but with a high local recurrence rate. Conversely, en bloc resection for aggressive lesions have lower local recurrence rates, but increased morbidity and possible functional impairment.

We would like to invite physicians and researchers involved in this field to contribute observations and results to this Special Issue.
